Starting in the 1950s, a number of experiments provided the experimental evidence supporting the original concept elaborated on by Hill and Lupton (12): in health, _VO2max in normoxia is limited primarily by cardiac output and locomotor muscle blood flow (17). The main variable accounting for the difference in _VO2max between sedentary subjects and athletes is maximal cardiac output, such that a linear relationship was observed between _VO2max and maximal cardiac output, showing that 5.9–7.5 l/min of cardiac output is needed per liter of _VO2max (5, 10, 17, 26). Part of the variability in the relationship between _VO2max and cardiac output was attributed to the variation in hemoglobin concentration, with a smaller contribution of the systemic a-v difference (5, 10, 17, 26). It was also shown that maximal exercise stroke volume was the main factor explaining the differences between subjects in maximal cardiac output (5, 10, 17, 26). A cause and effect relationship between oxygen delivery and _VO2max has been established by showing that experimental interventions increasing oxygen delivery are accompanied by an elevation of _VO2max and vice versa (6, 16).

All experimental procedures causing a reduction of maximal cardiac output are associated with a lower _VO2max. Reducing blood volume is associated with lower maximal cardiac output and _VO2max (16). Bed rest studies showed that the main factor accounting for the reduction in _VO2max was the lower maximal cardiac output attained after bed rest (27), because maximal exercise O2 fractional extraction is close to 90% after bed rest. Treatment with beta-blockers is accompanied by a reduction of maximal cardiac output and leg blood flow, which accounts for most of the reduction observed in _VO2max (21). The CaO2 may be reduced by decreasing hemoglobin concentration isovolumically and by carbon monoxide administration. These two interventions show a reduction in _VO2max that is proportional to the magnitude of the reduction achieved in CaO2 (6, 15, 23, 30).

The influence of locomotor muscle oxygen delivery for _VO2max in trained and untrained muscles was studied in the 1970s (3, 8, 28). With the use of a one-leg training model (in the cycle ergometer), Gleser (8) reported a 16% improvement of one-leg peak _VO2 that was accompanied by a 13% enhancement of the peak cardiac output during incremental exercise with the trained leg. However, neither _VO2max nor maximal cardiac output was enhanced after one-leg training when the exercise test was performed with the two legs. Thus the study by Gleser suggests that the increase in _VO2max was brought about via an enhancement of cardiac output and, likely, leg blood flow. Clausen et al. (3) reported a 10% greater peak _VO2 during arm cranking after a period of endurance training with the legs in the cycle ergometer. The increase in arm _VO2 was accompanied by 10 and 12% greater mean arterial pressure and peak cardiac output, also suggesting that _VO2peak during exercise with a small muscle mass is limited by locomotor muscle blood flow. In the study by Saltin et al. (28), the subjects that performed one-leg endurance training in the cycle ergometer improved their _VO2max by 24% during an incremental exercise to exhaustion with the trained leg. Interestingly, the contralateral leg that was not submitted to training also improved its _VO2max (6%). However, when the subjects carried out a two-legged incremental exercise the _VO2max was improved only by 11%. Thus the improvement observed during two-leg exercise was a bit less than expected if the limitation to _VO2max had been only of peripheral origin, suggesting that in that study part of the limitation to _VO2max during two-leg exercise is due to insufficient perfusion. A subsequent one-leg training study by Klausen et al. (13) adds further evidence. Their subjects trained each leg on the cycle ergometer individually. After the training, peak leg _VO2 during exercise on the cycle ergometer was 16% higher during one-leg than during two-leg exercise, due to a 23% higher peak leg blood flow during one-leg maximal exercise compared with two-leg maximal exercise. In contrast, before training, peak leg _VO2 was the same during one-leg cycling compared with two-leg cycling, despite the fact that leg blood flow was 8% higher during one-leg exercise. This study suggests that in the trained state, the dependency of _VO2max on oxygen delivery may be accentuated.

Further evidence for a cause and effect relationship between _VO2max and locomotory muscle oxygen delivery was obtained by Harms et al. (11). They showed that if the respiratory muscles are loaded, exercise capacity and locomotory muscle blood flow and _VO2 is reduced, suggesting that maneuvers redistributing part of the blood flow away from the locomotory muscles reduces exercise capacity and _VO2max (11) and vice versa. A similar conclusion was reached by Gonzalez-Alonso and Calbet (9). In their study, subjects performed constant intensity exercise to exhaustion under normothermic and hyperthermic conditions. In both conditions, fatigue was preceded by a reduction of cardiac output and leg blood flow. Moreover, we recently showed that during whole body upright exercise the combined maximal muscular vascular conductances of the limbs outweighs the pumping capacity of the heart in humans, meaning that _VO2max is limited by O2 delivery. With the use of data from the latter, we estimated that if the human with well-trained leg and arms muscles was able to use the full potential for _VO2 of the four limbs, then their _VO2max could be about 20% higher than actually measured (2).

Although _VO2max is a function of locomotor muscle blood flow, this does not exclude the possibility that other mechanisms marginally contribute to achieve _VO2max in normoxia, as, for example, exercise-induced arterial hypoxemia (4, 19), a diffusional limitation between the capillaries and the mitochondria of the active muscle fibers (24), and lower O2 extraction capacity in some muscles (1). However, in all these conditions, peak _VO2 is increased if the limitation is somehow overcome and more O2 is made available to the mitochondria (6, 14, 22, 25). Thus the bulk of the experimental evidence accumulated during the last 80 years argues in favor of cardiac output and oxygen delivery setting the limit for maximal oxygen uptake in normoxia. All these observations also argue against theories attributing the limitation of _VO2max to brain processes as the “Central Governor Model” during exercise in normoxia carried out by healthy subjects (20). This model postulates that processes arising in the brain itself, triggered or modulated by
sensory feedback, inhibit somehow the central command, causing the exercise to terminate (20). This model has revitalized some ideas brought about more than a century ago, as reviewed by Gandevia (7). However, experimental evidence obtained during exercise with hyperthermia (18) and during exercise in chronic hypoxia (29) demonstrated that, at least during brief efforts aimed at producing a maximal leg or hand grip voluntary contraction, the ability to recruit the motor units is preserved even when measured close to exhaustion.

In summary, in healthy humans, $V\dot{O}_2\text{max}$ at sea level is limited by systemic oxygen delivery and especially by $O_2$ delivery to the locomotor muscles. Oxygen delivery, in turn, depends on the ability of the cardiorespiratory system (i.e., lungs, heart, and blood) to transport and distribute appropriately $O_2$ to the active motor units, rather than on the mitochondrial oxidative capacity, which in human skeletal muscles exceeds widely maximal $O_2$ supply in all known exercise models.

Counterpoint: In health and in a normoxic environment, $V\dot{O}_2\text{max}$ is not limited primarily by cardiac output and locomotor muscle blood flow

Let’s begin this by being sure of the question we are addressing, because this topic is notorious for being easy to spin toward one’s desired position by subtly changing the question. I would like to clear the deck of spin right from the start. So I will stipulate that without blood flow, $V\dot{O}_2\text{max}$ would be zero: Saltin 1, Wagner 0. I will also stipulate that the venerable Fick Principle, taken at its naive simplest, would tend to support my opponent: $V\dot{O}_2 = Q \times [\text{CaO}_2 – \text{HbO}_2]$.
CVO₂), where Q is cardiac output, CaO₂ is arterial, and CVO₂ mixed venous [O₂]. I will even argue for him, comparing Lance Armstrong or equivalent with a sedentary normal subject each at their maximal exercise capacities, VO₂ would be about twice as high in LA (~80 vs. ~40 ml·kg⁻¹·min⁻¹). CaO₂ in the absence of erythropoietin would be close to 20 ml/dl in each, maybe even lower in LA if he shows exercise-induced desaturation (1) plus the plasma volume expansion, common in trained athletes, that results in a reduced [Hb] (16). CVO₂ would be lower in LA, perhaps as low as 2 ml/dl (i.e., 90% extraction) (5), whereas in his unfit couch potato (CP) counterpart, maximal extraction might not exceed 70% (12), with CVO₂ therefore at 6 ml/dl. Thus in the Fick equation above, maximal [CaO₂ – CVO₂] approximates 180 ml/l in LA and 140 ml/l in CP. This, in turn implies that LA’s peak Q must be 32 l/min, whereas CP’s is only 20 l/min (assuming both weigh ~70 kg). For LA, Q is 60% higher but [CaO₂ – CVO₂] is only 30% higher. So Bengt would be justified in saying Q is the primary determinant of VO₂ max if the question is “what primarily explains the difference in VO₂ max between CP and LA? Q or [CaO₂ – CVO₂]?” Saltin still 1.5, Wagner 0. (I will return to LA and CP later. Bengt, watch out.)

But, this is not the question that we are being asked to address. The question is: “Is cardiac output (or muscle blood flow) the primary determinant of VO₂ max or not?” Stated in other words, if a normal subject is exercising at VO₂ max and you were somehow able to augment any single part of the O₂ transport and use chain, what would this have on VO₂ max? And, would cardiac output, as one part of that chain, have the largest effect, as Bengt will argue? I hope he will not try and argue Q is the sole limiting factor, or I will blow him out of the water in rebuttal.

There is undeniable evidence that VO₂ max can be acutely altered at will in normal humans by any one of a number of interventions (8, 10, 14, 17, 21), of which altering Q is but one. Let’s step down the O₂ transport pathway, examining each step in turn.

Changing FIO₂ changes VO₂ max in the same direction (5, 6). Ventilation at VO₂ max is very hard to alter in normal subjects, but published theoretical models demonstrate that maximal O₂ transport and thus VO₂ max would be affected by changes in ventilation (20). VO₂/Q inequality (2), alveolar-capillary diffusion limitation (18), and (post) pulmonary shunts (2) can and do play a small but demonstrable role in reducing arterial oxygenation and thus VO₂ max. But suppose things are turned the other way around: maximal mitochondrial O₂ use potential now exceeds O₂ availability. Then, according to the evidence presented above, augmenting each and every step in O₂ transport should have a positive effect on VO₂ max, and it does. Suppose each component is augmented by 20% of its value, one at a time. Integrated physiological models incorporating all pathway steps (20) and Fig. 1 show that a 20% increase in FIO₂ raises VO₂ max by only 5.0%, due to the flat O₂-Hb dissociation curve in the normal range. Increasing ventilation 20% will also lead to a small (1.3%) increase, again because PO₂ is on the flat part of the curve, and raising P O₂ has little effect on CaO₂. Increase lung diffusing capacity 20% in an athlete who has mild hypoxemia due to diffusion limitation and VO₂ max will increase by 2.9%. Increasing diffusing capacity in a subject without diffusion limitation obviously cannot improve VO₂ max. If skeletal muscle O₂ diffusional conductance is increased by 20%, VO₂ max will be 5.0% higher. Increase [Hb] by 20% and VO₂ max increases by only 3.9%. Finally, increase Q by 20%, and VO₂ max increases by only 2.6%, half that when muscle O₂ conductance is raised equally. Why? Because muscle O₂ conductance has only one significant effect—to increase O₂ flux from blood to cells. But raising Q has opposing effects (19). First, it increases convective O₂ transport by the circulation as predicted by both Bengt and the Fick principle. But the higher Q simultaneously reduces transit time in both lung

![Fig. 1. Calculated effects of individual changes in key O₂ transport variables on VO₂ max. Data reflect typical normal sea level values. Calculations use the model are described in Ref. 20. Note that all variables affect VO₂, and that QT is by no means the most important factor.](http://jap.physiology.org/content/jappl/100/2/746/F1.full)
and muscle capillaries and this worsens diffusion limitation, significantly opposing this convective gain.

This brings me back to LA and CP as promised. If LA did not have a superior muscle O₂ conductance to facilitate O₂ transport to cells, the 32 l/min Q would simply limit O₂ extraction due to rapid red cell transit. The only way LA can get to 80 ml/min VO₂ max is by having both an exceptional Q and a matching, exceptional muscle capillary-to-mitochondriod O₂ transport system to permit almost full O₂ extraction from the rapidly flowing blood. Thus, even if Bengt argues from the Fick Principle, as in my opening paragraph, the untold story is that muscle O₂ conductance must also be extraordinary, every bit as important as Q, or O₂ extraction could not possibly reach 90%. I rest my case, Bengt: Saltin 1.5, Wagner 10.

REBUTTAL FROM DRS. SALTIN AND CALBET

The diffusional limitation theory is based primarily on one study (8) where an extraordinary elevation of leg VO₂peak (39%) and whole body (WB) VO₂ max (35%) was observed after 6 wk of training (Ref. 8, p. 1070), whereas maximal exercise intensity was only enhanced by 9%. Leg VO₂ only accounted for 53–55% of WB VO₂ at maximal exercise (before-after training), i.e., far below the normal 75–85% (5). These low leg peak VO₂ values were likely caused by underestimation of peak leg blood flow (BF; which was only 5–6 l/min). Because during WB exercise, systemic a-v difference is never higher than leg a-v difference, peak cardiac output should have been >19 l/min before training and >23 l/min after training (+20%), leaving 9–10 l/min of BF for the rest of the body, which is too high a figure (5). Because DO₂ (oxygen conductance) is calculated as peak leg VO₂/mean capillary PO₂ (PmcO₂) (10), it is likely that DO₂ was also underestimated (8).

Could a “couch potato” (CP) enhance his VO₂ max by increasing his cardiac output and BF? CP should be able to achieve an arm BF of ~2.5–3 l/min with an O₂ extraction a bit lower in the arms than the legs during maximal exercise (1–3, 7). This means that the VO₂peak of CP arms could reach 0.6–0.7 l/min. To perform maximal exercise with the four extremities, CP will need to increase his maximal cardiac output from 20 to 24 l/min. With the extra perfusion, CP could achieve a VO₂ max 20% greater, even when assuming a lower muscle diffusing capacity in the arms than in the legs (2). CP could also increase his VO₂ max after blood transfusion or treatment with EPO. After this intervention, PmcO₂ will be similar or a bit higher (6), meaning that the increase of VO₂ max requires an increase of DO₂ after transfusion or EPO. If for a given PmcO₂, DO₂ is enhanced when [Hb] is increased, it implies that VO₂ max is not limited by a structural resistance to diffusion in the skeletal muscle of healthy humans, i.e., what Roughton and Forster called membrane component of the oxygen conductance (9). Thus, for DO₂ to be the key limiting factor for VO₂ max first the evidence that DO₂ actually represents the maximal attainable oxygen diffusing capacity in skeletal muscles should be provided. However, we agree that a diffusion limitation theoretically is a possibility but functionally it is a very minor player in healthy humans (4).

REBUTTAL FROM DR. WAGNER

My good friends Bengt and Jose have done a wonderful job of making my case and my rebuttal easy, because we clearly agree on several points. We agree that cardiac output/muscle blood flow is one determinant of maximal VO₂. We agree that one major difference between an athlete and a couch potato is in maximal cardiac output. However, we surprisingly agree that other factors contribute substantially to maximal VO₂. Bengt and Jose say this in paragraph 2 referring to the role of CaO₂, which is not blood flow and restate this in their concluding paragraph, agreeing that lungs, heart, and blood are all important, just as I have argued. But they cannot use this to advance their own argument because the topic was not about O₂ delivery, it was about blood flow.

I must also remind my friends that the topic includes the word primarily. They provided no evidence that per unit of change in the responsible variable, blood flow is the primary factor, more important than any other conductances in the O₂ transport chain. They have failed to realize that for a high cardiac output to allow a high VO₂ max, the diffusing capacities in both the lungs and muscles must be correspondingly high, or pulmonary O₂ loading and tissue unloading must be compromised, as pointed out many years ago by Piiper et al. (1, 2). They have assigned primary importance to one variable (flow) without assessing all other pertinent variables. How can you compare the roles of each variable when not all are addressed? Suppose you ask which is the fastest way to get from point A to B? By car, bicycle, or plane, and don’t even study other alternatives such as by train or on foot. You simply cannot conclude that by train or on foot are not faster ways to get there. By looking at only part of the story, they have presented only part of the answer.
