West DW, Burd NA, Tang JE, Moore DR, Staples AW, Holwerda AM, Baker SK, Phillips SM. Elevations in ostensibly anabolic hormones with resistance exercise enhance neither training-induced muscle hypertrophy nor strength of the elbow flexors. J Appl Physiol 108: 60–67, 2010. First published November 12, 2009; doi:10.1152/japplphysiol.01147.2009.—The aim of our study was to determine whether resistance exercise-induced elevations in endogenous hormones enhance muscle strength and hypertrophy with training. Twelve healthy young men (21.8 ± 1.2 yr, body mass index = 23.1 ± 0.6 kg/m²) trained their elbow flexors independently for 15 wk on separate days and under different hormonal milieu. In one training condition, participants performed isolated arm curl exercise designed to maintain basal hormone concentrations (low hormone, LH); in the other training condition, participants performed identical arm exercise to the LH condition followed immediately by a high volume of leg resistance exercise to elicit a large increase in endogenous hormones (high hormone, HH). There was no elevation in serum growth hormone (GH), insulin-like growth factor (IGF-1), or testosterone after the LH protocol but significant (P < 0.001) elevations in these hormones immediately and 15 and 30 min after the HH protocol. The hormone responses elicited by each respective exercise protocol late in the training period were similar to the response elicited early in the training period, indicating that a divergent postexercise hormone response was maintained over the training period. Muscle cross-sectional area (CSA) increased by 12% in LH and 10% in HH (P < 0.001) with no difference between conditions (condition × hormone interaction, P = 0.25). Similarly, type I (P < 0.01) and type II (P < 0.001) muscle fiber CSA increased with training with no effect of hormone elevation in the HH condition. Strength increased in both arms, but the increase was not different between the LH and HH conditions. We conclude that exposure of loaded muscle to acute exercise-induced elevations in endogenous anabolic hormones enhances neither muscle hypertrophy nor strength with resistance training in young men.

HORMONES such as testosterone, growth hormone (GH), and insulin-like growth factor-1 (IGF-1) are important for skeletal muscle anabolism during growth and development (e.g., 23). It has been suggested that acute elevation of this triumvirate of hormones that occurs after performance of intense resistance exercise is a significant contributor to the gains in strength and hypertrophy that are observed with resistance training (14, 19, 24, 30). The magnitude of the increase in concentration of these hormones is largely dependent on parameters of the resistance exercise. Specifically, large elevations of systemic hormones are observed acutely postexercise after resistance exercise bouts consisting of a high amount of work (8, 9, 28). Additionally, higher intensity exercise (16, 19) with short rest intervals (4, 17) that is performed with large muscle groups (10, 19) are also associated with large rises in these hormones. In fact, training principles have been constructed to maximize the postexercise rise in these hormones based on the interpretation that exercise-induced increases in systemic hormones like testosterone and GH will enhance muscle hypertrophy (15, 27, 31). Specifically, it has been suggested that small exercising muscle groups (e.g., biceps brachii), which are incapable of inducing large increases in systemic anabolic hormones when used in isolation, should be trained concurrently with large exercising muscle masses that can elevate testosterone and GH (10, 19). However, the hypothesis that exercise-induced rises in testosterone and GH enhance increases in strength and muscle hypertrophy with training remains untested.

We have previously demonstrated that acute changes in muscle protein synthesis following resistance exercise and feeding (38) can qualitatively predict gains in muscle fiber cross-sectional area (CSA) and lean body mass (11). Recently, we have shown that exercise-induced hormones that are hypothesized to be anabolic and affect hypertrophy do not acutely enhance fed-state myofibrillar protein synthesis after acute resistance exercise (36). Despite the ability of the postexercise protein synthetic response (38) to predict phenotypic adaptions to training (11), it is unknown whether the synthetic responses that we observed after a single acute bout of exercise (36) would ultimately translate into similar increases in muscle size and strength when hormone availability is manipulated following repeated bouts of resistance exercise (i.e., training). Thus the aim of our present study was to determine if increases in muscle strength and hypertrophy are enhanced by exercise-induced increases in hormone availability with resistance training. Based on our previous acute finding that myofibrillar protein synthesis was not enhanced by acute elevations in circulating testosterone, GH, and IGF-1, we hypothesized that repeatedly elevating the acute postexercise availability of these hormones would not enhance the muscle hypertrophy and strength gains achieved from a progressive resistance training program. Previous work demonstrating an effect of elevated endogenous hormones on gains in isometric strength has used a similar design (10). Thus, as a reasonable proof of principle study, if acute rises in GH, IGF-1, and testosterone were to result in differential phenotypic changes, then an inherently superior design for testing this thesis is a unilateral within-person design, where interindividual differences in potential for hypertrophy and strength gains, which are substantial (12), are minimized.
METHODS

Subjects. Twelve healthy young men (21.8 ± 0.4 yr, 1.78 ± 0.02 m, 74.1 ± 3.3 kg; means ± SE) volunteered to participate in the study after being informed of the procedures and potential risks involved in the investigation. Subjects were recreationally active with no formal weightlifting experience. Participants provided consent to an agreement that was approved by the Research Ethics Board of Hamilton Health Sciences and that was written in accordance with standards set by the Declaration of Helsinki.

Experimental protocol. Using a within-person design, participants trained each arm on separate days under two different hormonal environments for 15 wk. In the low hormone condition (LH), one arm performed arm curl exercise only, while in the high hormone condition (HH) the contralateral arm performed the same arm curl exercise followed immediately by a bout of leg resistance exercises designed to elicit large increases in circulating hormones. In weeks 1–6, participants trained each arm three times per 2 wk; they trained in a manner that allowed 72 h between LH and HH training days (e.g., week 1: Monday*, Tuesday, Friday*; week 2: Monday, Thursday*, Friday; HH session days shown with asterisk). This approach was taken to ensure that the enhanced muscle protein synthetic response, which can be elevated in the untrained state for ~48 h (22, 26), occurred exclusively on the background of basal hormone concentrations during LH before the hormonal spike that was associated with exercise on the HH day 72 h later. In weeks 7–15, an extra training session was added to enhance the training stimulus so that each arm trained twice per week with at least 48 h following each arm-only trial (e.g., week 7: Monday*, Tuesday, Thursday*, Friday; HH session days shown with asterisk). We have previously shown that resistance training shortens the duration (i.e., <28 h) for which muscle protein synthesis is elevated after exercise (33). Therefore, despite the inclusion of an additional training session per week, the attenuated time course of muscle protein synthesis after exercise in a more trained state would still have provided enough recovery to ensure that the LH arm was not exposed to the hormonal milieu of HH during the skeletal muscle remodeling process. Participants consumed 18 g of whey protein immediately before exercise and 18 g at 90 min after arm exercise in each condition to support maximal rates of muscle protein synthesis both in the absence and presence of elevated hormone concentrations as well as to reduce variability in nutrition surrounding the exercise bout.

Training. Subjects were familiarized with each exercise before strength testing and beginning the training program. Exercise in LH consisted of three to four sets of 8–12 repetitions at a load that was ~95% of their 10-repetition maximum (RM) such that voluntary failure occurred during the final set. Exercise in HH was performed in the contralateral arm and consisted of identical arm exercise to LH but was followed by five sets of 10 repetitions of leg press and three sets of 12 repetitions of leg extension/leg curl “supersets” (1 set of each exercise, back-to-back, with no rest between sets) at ~90% of 10 RM. Between-set rest intervals for arm and leg exercises were 120 and 60 s, respectively. Participants followed a progressive training protocol with respect to the number of sets and repetitions and to the load that was lifted. Each training session was supervised individually, and compliance across 56 sessions (28 per arm) was 96%. Subjects trained each arm three times over 2 wk; they trained in a manner that allowed 72 h between LH and HH training days (e.g., week 1: Monday*, Tuesday, Friday*; week 2: Monday, Thursday*, Friday; HH session days shown with asterisk). This approach was taken to ensure that the enhanced muscle protein synthetic response, which can be elevated in the untrained state for ~48 h (22, 26), occurred exclusively on the background of basal hormone concentrations during LH before the hormonal spike that was associated with exercise on the HH day 72 h later. In weeks 7–15, an extra training session was added to enhance the training stimulus so that each arm trained twice per week with at least 48 h following each arm-only trial (e.g., week 7: Monday*, Tuesday, Thursday*, Friday; HH session days shown with asterisk). We have previously shown that resistance training shortens the duration (i.e., <28 h) for which muscle protein synthesis is elevated after exercise (33). Therefore, despite the inclusion of an additional training session per week, the attenuated time course of muscle protein synthesis after exercise in a more trained state would still have provided enough recovery to ensure that the LH arm was not exposed to the hormonal milieu of HH during the skeletal muscle remodeling process. Participants consumed 18 g of whey protein immediately before exercise and 18 g at 90 min after arm exercise in each condition to support maximal rates of muscle protein synthesis both in the absence and presence of elevated hormone concentrations as well as to reduce variability in nutrition surrounding the exercise bout.

Training. Subjects were familiarized with each exercise before strength testing and beginning the training program. Exercise in LH consisted of three to four sets of 8–12 repetitions at a load that was ~95% of their 10-repetition maximum (RM) such that voluntary failure occurred during the final set. Exercise in HH was performed in the contralateral arm and consisted of identical arm exercise to LH but was followed by five sets of 10 repetitions of leg press and three sets of 12 repetitions of leg extension/leg curl “supersets” (1 set of each exercise, back-to-back, with no rest between sets) at ~90% of 10 RM. Between-set rest intervals for arm and leg exercises were 120 and 60 s, respectively. Participants followed a progressive training protocol with respect to the number of sets and repetitions and to the load that was lifted. Each training session was supervised individually, and compliance across 56 sessions (28 per arm) was 96%.

Muscle fiber CSA. Muscle biopsies were performed pre- and posttraining with a 5-mm Bergström needle that was custom modified for manual suction under local anesthesia (2% xylocaine). Muscle fibers were oriented vertically under a dissecting microscope and embedded in optimal cutting temperature (OCT) medium. The mounted muscle was frozen in isopentane cooled by liquid nitrogen and stored at −80°C until processing for CSA analysis. Cross sections (10 μm thick) were cut, mounted on glass slides, and stained using a myofibrillar ATPase histochemistry procedure at an acid preincubation pH of 4.6 to distinguish type I and type II fibers as described previously (13, 32). Pictures of the stained slides were taken using a light microscope and NIS Elements 3.0 Imaging Software (Nikon, NY). An average of 47 type I and 53 type II fibers were circled using ImagePro Plus software (version 4.5.1.22, Media Cybernetics, Bethesda, MD) to quantify CSA. During the course of analysis our freezer malfunctioned, which compromised the quality of some of our samples. Since the study was a within-subject design with pre- and posttraining biopsies, if one or more of four samples (pre-LH and pre-HH; post-LH and post-HH) was of poor quality it prevented us from being able to make within-subject comparisons. Thus we have only included data for subjects (n = 7) for whom we could obtain a complete data set from both arms pre- and posttraining.

Statistics. This study was a within-subject repeated-measures design. Blood lactate and serum hormone concentrations were analyzed...
using three-factor repeated-measures ANOVA statistics with training (pre and post), condition (LH and HH), and time (preexercise and 0, 15, 30, and 60 min postexercise) as within-subject factors. Two-factor (training × condition) repeated-measures ANOVA was used to analyze area under the curve data; two-factor (time × condition) repeated-measures ANOVA was used to analyze hematocrit and plasma volume change early in the training period. One-factor (time) repeated-measures ANOVA was used to analyze mean insulin and amino acid concentrations across training in each condition. Hypertrophy and strength data were analyzed using two-factor (training × condition) repeated-measures ANOVA. Hypothetical titles could be: A) Lactate concentrations, B) Growth hormone (GH), C) IGF-1, D) Testosterone, E) Free testosterone, F) Cortisol.

Fig. 1. Whole blood lactate (A) and serum growth hormone (GH; B), IGF-1 (C), total testosterone (D), free testosterone (E) and cortisol (F) concentrations at rest and after low hormone (LH) and high hormone (HH) exercise protocols. Insets: net area under the curve (AUC; rest = 0); closed bars, HH; open bars, LH. Significantly greater than LH for corresponding time points and for AUC, *P < 0.01, †P < 0.001. Values are means ± SE.

Values are means ± SE. Hematocrit: there was a greater increase in hematocrit after the high hormone (HH) protocol (condition × time interaction, \( P < 0.001 \)). Different from low hormone (LH) at same time: †\( P < 0.05 \), ‡\( P < 0.001 \). Plasma volume: there was a greater decrease in plasma volume after the HH protocol (condition × time interaction, \( P < 0.001 \)). †Different from LH at same time, \( P < 0.01 \).

repeated-measures ANOVA. Where ANOVA revealed significance (\( P < 0.05 \)), Tukey’s post hoc test was used to identify pairwise differences. Values are expressed as means ± SE.

RESULTS

Blood analyses. LH elicited a minimal rise in lactate concentration (~2 mmol/l at peak), whereas HH elicited a marked increase (~10.5 mmol/l at peak); nearly identical responses were elicited before and after training within each condition (Fig. 1A). Figure 1, B–E, shows the hormone responses of GH, IGF-1, and total and free testosterone, respectively, after each condition during the first and last weeks of training. There was no change in the concentration of any of these hormones after exercise in LH. In contrast, there was a marked increase in GH, IGF-1, and total and free testosterone that peaked ~15 min after HH (\( P < 0.001 \)); this divergent pattern in hormone availability was present both at the beginning and end of 15 wk of training. Cortisol concentrations were similar to basal levels before and after HH with training (\( P < 0.001 \)), but there were no differences between conditions (condition × training interaction, \( P = 0.65 \)). Similarly, 1 RM increased 23 ± 6% (2–56%) in LH and 25 ± 5% (2–53%) in HH (\( P < 0.001 \), Fig. 2A) with no effect of condition (\( P = 0.43 \)). The 10 RM increased 46 ± 3% (33–62%) in LH and 47 ± 6% (20–100%) in HH (\( P < 0.001 \), Fig. 2B); there were no differences between conditions (\( P = 0.63 \)).

Muscle fiber and elbow flexor CSA. Type I muscle fiber CSA increased 9 ± 3% (0–16%) in LH and 11 ± 4% (0–26%) in HH with training (\( P < 0.01 \), Fig. 3A) while type II muscle fiber CSA increased 21 ± 4% (8–42%) in LH and 24 ± 6% (9–53%) in HH (\( P < 0.001 \), Fig. 3B); there were no differences between conditions for either fiber type (condition × time interaction, \( P = 0.96 \)).

Values are means ± SE in \( \mu \)M for amino acids (AA) and in \( \mu \)IU/ml for insulin. Blood sample time points in this table are referenced to the protein drink that participants consumed immediately before exercise and therefore do not match the time points in the hormone graphs that are referenced to the end of exercise (e.g., Fig. 1). Because the length of the HH exercise bout was ~15 min, longer than the LH bout, blood samples are only available for select time points and were analyzed within condition. For amino acids, there was a main effect for time in each condition for branched chain AA (BCAA), essential AA (EAA), and total AA (all \( P < 0.001 \)) where different superscript letters indicate significantly different means (\( P < 0.05 \)). For insulin, there was a main effect for time in HH and LH (\( P < 0.05 \) and 0.001, respectively) where different superscript letters indicate significantly different means (\( P < 0.05 \)).
we found no differences in the increases in strength or hyper-
in hormone availability in the immediate postexercise period,
androgen concentration. The contralateral arm was exposed
marked increases in GH, IGF-1, as well as total and free
available for protein synthesis, one arm was repeatedly exposed to
endogenous hormone concentrations so that, during the acute
postexercise time period when amino acids were readily avail-
able for muscle anabolism. It is important to note that the transient
elevation that is observed with pharmacological administra-
tion, which can have an effect on overall muscle mass depend-
ing on the hormone. For example, supraphysiological doses of
exercise-induced hormones, are unclear but are more likely
induced hormones, as well as the biological relevance of
training. The mechanisms that drive increases in exercise-
induced hormone elevations do not stimulate myofi-
brillar protein synthesis (36) and are not necessary for hyper-
trophy (37). Thus our data (36 and present observations), when
viewed collectively, lead us to conclude that local mechanisms
are of far greater relevance in regulating muscle protein accre-
tion occurring with resistance training and that acute changes
in hormones, such as GH, IGF-1, and testosterone, do not
predict or in any way reflect a capacity for hypertrophy.

We found no additional strength improvements in the arm
trained under the HH condition, which is in contrast to a study
(10) that is commonly cited (e.g., 14, 18–20, 30, 31) to support
the thesis that exercise-induced increases in hormone availability
enhance training adaptations. However, the finding of
greater isometric strength gains due to physiological hormone
elevations in the previous study (10) may have been related to
differences in baseline strength between different groups training
with either low or high hormone concentrations. In the present
study there was no difference between arms in any of
our measures of strength before or after training. Moreover, in
agreement with our data, Hansen and co-workers (10) reported
no effect of exercise-induced rises in hormone levels on dy-
namic strength gains with training. Since our study was a
within-subject design, we can expect that a portion of the
increase in strength was due to cross-education effects, i.e.,
increased strength in the limb that is contralateral to the
training limb, which is ~7% of initial strength in the elbow
flexors (5). Additionally, any contribution to increased strength
due to cross-education would have likely benefited both arms
similarly and is a reflection of increased motorneuron output
rather than muscular adaptations (6).

In addition to measuring changes in strength, we quantified
whole muscle and fiber CSA to determine if exercise-induced
elevations in circulating hormones enhances muscle hypertro-
phy with resistance training. We found no effect of elevated
hormones on the degree of muscle hypertrophy measured by
either MRI or histochemical staining with 15 wk of training.
Instead, our data showed virtually identical increases in both
muscle fiber and whole muscle CSA regardless of hormonal
condition. These findings agree with the notion that local and
not systemic factors are responsible for initiating signaling
responses in type I and II fibers in response to resistance
exercise (34).

By strictly supervising each session of a progressive training
program, we successfully maintained divergent hormone pro-
files in the acute recovery period after exercise. That is, LH and
HH elicited low and high hormone (and lactate) responses,
respectively, at both the beginning and through to the end of
training. The mechanisms that drive increases in exercise-
induced hormones, as well as the biological relevance of
exercise-induced hormones, are unclear but are more likely
related to metabolic stress and/or fuel mobilization rather than
muscle anabolism. It is important to note that the transient
physiological increase in hormone availability that can occur
after resistance exercise is in contrast to the continued marked
elevation that is observed with pharmacological administra-
tion, which can have an effect on overall muscle mass depend-
ing on the hormone. For example, supraphysiological doses of
testosterone are clearly potently anabolic to skeletal muscle (3)
whereas GH supplementation has little effect on the exercise-induced increase in muscle mass (39). Furthermore, there is evidence that a minimal basal level of testosterone is required to support strength and hypertrophy gains, which are otherwise attenuated (20). Therefore, the hormone-sensitive processes that underpin muscle anabolism at hypo- and supraphysiological hormone levels are not being activated appreciably by exercise-induced increases in hormone availability or at least do not result in any measurable enhancement of strength or hypertrophy.

In our view, resistance exercise provides an intrinsic stimulus to the working muscle, which drives hypertrophy, and whereas physiological systemic hormone concentrations may be permissive for the hypertrophic process, exercise-induced elevations do not enhance or in any way predict hypertrophy. These data (2, 35) suggest that local mechanisms within the muscle are of paramount importance in determining muscle hypertrophy. Clearly further research is required to clarify how these mechanisms, possibly in concert with local growth factors (1), combine with other mechanical signals to stimulate muscle protein synthesis and facilitate muscle protein accretion. Ultimately, muscle hypertrophy is specific to the trained muscle group, and strength adaptations are specific to the characteristics of the training regime (29); our data suggest that these adaptations are dissociated from acute exercise-induced hormonal rises.

In summary, transient resistance exercise-induced increases in endogenous purportedly anabolic hormones do not enhance muscle strength or hypertrophy following 15 wk of resistance training. Instead, our data are consistent with the notion that local mechanisms are of primary relevance in producing gains
in muscle strength and hypertrophy with resistance training. These findings, combined with our previous work (36, 37), provide multiple lines of evidence that exercise-induced elevations of purportedly anabolic hormones are not necessary for, and do not enhance, muscle anabolism in young men. Our data indicate that exercise-induced changes in concentrations of systemic hormones do not reflect the underlying processes of muscle protein accretion and cannot be used as a proxy marker of muscle hypertrophy.

ACKNOWLEDGMENTS

We thank Todd Prior and Tracy Rerecich for technical assistance and our participants for their time and effort. We are grateful to Gianni Parise and Warren Foster for use of equipment for muscle fiber analysis and to Dean Inglis and Jonathan Adachi for assistance with MRI.

GRANTS

This work was supported by a Natural Science and Engineering Research Council (NSERC) of Canada grant to S. M. Phillips. D. W. D. West, J. E. Tang, A. W. Staples, and D. R. Moore are Canadian Institutes of Health Research (CIHR) Canada Graduate Scholarship Award recipients, and all authors acknowledge those sources of support during the conduct of this research.

DISCLOSURES

No conflicts of interest are declared by the authors.
