Submitted 19 March 2012; accepted in final form 13 September 2012

Intracranial pressure pulse waveform correlates with aqueductal cerebrospinal fluid stroke volume. J Appl Physiol 113: 1560–1566, 2012. First published September 20, 2012; doi:10.1152/japplphysiol.00357.2012.—This study identifies a novel relationship between cerebrospinal fluid (CSF) stroke volume through the cerebral aqueduct and the characteristic peaks of the intracranial pulse (ICP) waveform. ICP waveform analysis has become much more advanced in recent years; however, clinical practice remains restricted to mean ICP, mainly due to the lack of physiological understanding of the ICP waveform. Therefore, the present study set out to shed some light on the physiological meaning of ICP morphological metrics derived by the morphological clustering and analysis of continuous intracranial pulse (MOCAIP) algorithm by investigating their relationships with a well defined physiological variable, i.e., the stroke volume of CSF through the cerebral aqueduct. Seven patients received both overnight ICP monitoring along with a phase-contrast MRI (PC-MRI) of the cerebral aqueduct to quantify aqueductal stroke volume (ASV). Waveform morphological analysis of the ICP signal was performed by the MOCAIP algorithm. Following extraction of morphological metrics from the ICP signal, nine temporal ICP metrics and two amplitude-based metrics were compared with the ASV via Spearman’s rank correlation. Of the nine temporal metrics correlated with the ASV, only the width of the P2 region (ICP-Wi2) reached significance. In this study, we showed the width of the second peak (ICP-Wi2) of an ICP pulse wave is positively related to the volume of CSF movement through the cerebral aqueduct. This finding is an initial step in bridging the gap between ICP waveform morphology research and clinical practice.

intracranial pressure; normal pressure hydrocephalus; cerebrospinal fluid; intracranial dynamics; phase-contrast MRI

IT IS WELL ACCEPTED THAT THE SHAPE of the intracranial pressure (ICP) waveform arises as a result of the interaction between the pulsatile cerebral blood flow (CBF) pulse and complex intracranial compartment (3, 5, 8). Typically, the individual ICP waveform is triphasic (24). Early physiological studies concerning the origins of ICP pulse suggested that the first peak of ICP pulse mainly reflects the pulsations of large intracranial conductive arteries and that the third peak of an ICP pulse mainly reflects venous pulsation (2, 24). Logically, one might conclude that the second peak (P2) might represent the cerebral vascular pulsations in the capillary or brain parenchymal phase.

The dynamic, pulsatile movement of intracranial cerebrospinal fluid (CSF) is also highly coupled to CBF (40): specifically, the differential arterial vs. venous intracranial blood volumes occurring during each cardiac pulse. Using careful MRI measurements, Greitz et al. demonstrated that the caudally directed aqueductal movement of CSF is predominantly caused by the blood volume brain expansion, i.e., the capillary filling phase (21).

In the early 1990s, Bradley et al. (7) found a correlation between normal pressure hydrocephalus (NPH) shunt responsiveness and cerebral aqueduct CSF flow velocity. Although other studies revealed inconsistent results with regard to the positive predictive value of this parameter (12, 31), aqueductal stroke volume (ASV) has been used in a wide range of studies (34, 38), including recent work that shows changes in ASV with age (39) and therefore likely represents a fundamental physiological feature. The underlying physiological basis for increased aqueductal CSF flow in hydrocephalus is unknown, but its existence suggests that pulsatile CSF dynamics is key to hydrocephalus pathophysiology.

For several years, our laboratory has been seeking to understand the possible role of pulsatile CSF dynamics in the pathophysiology of hydrocephalus (27). The basic premise is that CSF volumetric buffering is essential for transmission of pulsatile CBF within the cranium. Greitz (21) established the concept that, in normal circumstances, the majority of pulsatile CSF volume buffering occurred within the basal cisterns driven by a cranial-caudal piston action of the brain in response to blood volume changes. A second type of brain movement, inward implosion of the hemispheres, results in a smaller ventricular CSF movement. We proposed that so-called “communicating” hydrocephalus arose from interference of dynamic cisternal CSF movement, a situation that would be difficult to distinguish from the traditional concept of impaired CSF absorption (33). The decreased cisternal CSF buffering capacity would be compensated by an increase in ventricular buffering. This would manifest as an increase in aqueductal CSF stroke volume, which is exactly what Bradley et al. and others found (7, 11, 34).

Here, we examined the possible relationship between ICP waveform morphology and MRI CSF flow dynamics in a group of hydrocephalus patients that had both been directly measured. We hypothesized that characteristics of the P2 peak would be more closely tied to measures of aqueductal CSF flow than the other ICP peaks (P1 and P3). The accurate...
measurement of ICP waveform morphology requires robust waveform extraction techniques. Our group and others have done a series of work in advancing the techniques of ICP signal analysis (10, 15, 18, 25, 30, 36). We developed the Morphological Clustering and Analysis of Continuous Intracranial Pulse (MOCaIP) algorithm (30), through which one can first robustly identify the locations of the three subpeaks and troughs of an ICP pulse and then systematically extract additional metrics on the ICP morphology. Studies have been conducted using these MOCaIP metrics to detect acute cerebral ventricular enlargement (29), predict acute ICP hypertension (23, 28), detect cerebral hypoperfusion (26), segment overnight ICP slow waves (32), and characterize acute cerebrovascular changes (4). To quantify CSF hydrodynamics in this patient population, CSF movement through the cerebral aqueduct was measured using phase-contrast MRI (PC-MRI) (19).

METHODS

Patient characteristics and data acquisition. While under evaluation for NPH at the UCLA Adult Hydrocephalus Center, seven patients received both overnight ICP monitoring and a PC-MRI CSF flow protocol. Patients were recommended for extended lumbar drain trial (ELD) based on presence of the clinical triad (gait ataxia, urinary incontinence, and dementia); however, progressive gait ataxia was the most common symptom. All ICP sensor and data acquisition (both imaging and pressure monitoring) were approved by the local IRB committee, and all subjects signed informed consent to participate. All measurements were taken while the patient was in the supine position.

Phase-contrast imaging. Seven patients (71.1 ± 9.8 yr) received the imaging protocol, which either preceded admission for ELD or followed the ELD by no less than 3 wk, which allowed for equilibration of the baseline hydrodynamics. For patients that had temporarily improved after the ELD trial, all had completely reverted back to their original state at least 2 wk before the MRI study. Patient manuscript ID, age, and sex characteristics are shown in Table 1, all patients showed temporary improvement from ELD along with an average Evan’s ratio of 0.35 ± 0.04. All MRI scans were performed using a 3-T Siemens Trio T-class MRI (Siemens Medical Systems, Erlanger, Germany). Using a Siemens Head Matrix bird cage head coil, the participants were placed in the supine position with their neck and head in the neutral position. Phase-contrast imaging took place in the cerebral aqueduct. The imaging protocol contained both anatomical and flow quantification sequences. The standard anatomical sequences included a three-dimensional axial T1-weighted MPRage (1,900 ms/3.4 ms/900 ms/0.84 mm/0.90 mm; TR/TE/TI/resolution/slice thickness), and a sagittal T2-weighted Turbo spin echo (TSE) sequence (750 ms/100 ms/0.34 mm/8 mm).

Flow quantification was achieved using a standard phase-contrast sequence. An oblique plane was defined perpendicular to the presumed direction of CSF flow (Fig. 1). The velocity encoding parameter (Venc) was set with the aid of a flow scout to reduce aliasing. Following the definition of the Venc, the phase-contrast sequence (39.1 ms/0.61 ms/0.63 mm3/3 mm) was applied. The average and standard deviation of the Venc for the seven patients was 17.4 ± 4.4, respectively with a range from 12 to 25 cm/s. Finally, a temporal resolution of 30 frames was defined with retrospective gating with either ECG or pulse oximetry signals.

Overnight ICP monitoring. During the overnight monitoring, patients assumed a supine or near supine position. An intraparenchymal ICP microsensor (Codman and Schurtleff, Raynau, MA) was inserted in the right frontal lobe and continuously monitored ICP one night before the placement of the lumbar drain (LD). Continuous waveform data, including ECG and ICP, was captured using the BedMaster system (Excel Medical Electronics, Jupiter, FL) with a sampling rate of 240 Hz. Following overnight monitoring, the intraparenchymal ICP monitor was removed, and the patient was transitioned into the ELD trial.

Data analysis. For the imaging data, a semi-automated segmentation algorithm was implemented for the designation of the region of

Spearman’s rank correlation coefficient (r) for the aqueductal stroke volume. The metrics are divided into three regions defined by the characteristic ICP pulse waveform peaks (columns P1, P2, P3) and by temporal category (rising time, falling time, and peak width time). *Significant correlations (P < 0.05).

interest (ROI). The algorithm was developed using MATLAB 7.5 R2007b (The MathWorks, Natick, MA), which utilized both anatomical and dynamic information from the phase-contrast study (22). Following the extraction of the ROI, the hydrodynamic metric ASV was calculated as the average of the volume moving in the cranial-caudal and caudal-cranial direction over the cardiac cycle, which represents the net volume through the aqueduct (7).

The ICP waveform morphology characterization was done using the MOCAIP analysis toolbox. MOCAIP provides a real-time, time-domain analysis of intracranial waveform morphology (30). MOCAIP utilizes a five-step process to analyze the raw ICP and ECG inputs (if ECG is not available, pulse detection can still be done using a modified algorithm) into a series of clean valid ICP pulses (known as a dominant pulse) based on a segment of raw data. First, ECG is used to segment the raw ICP signal into a series of pulses. Following the pulse segmentation, a segment of pulses (1-min segment in this study) is clustered using a hierarchical clustering method, which defines the dominant pulse of the cluster as the mean of the largest cluster. This alone, however, could still produce an invalid ICP pulse (dominant pulse) because the entire segment could be noise; therefore, the segment’s dominant pulse is checked against a reference ICP pulse library to determine the legitimacy of the pulse. Once the dominant pulse has been verified, six landmarks are determined, the three characteristic peaks and their corresponding valleys. The automated process for identifying these peaks has evolved over time, and details can be found in previous publications (37). Following the identification of the landmarks, 128 MOCAIP metrics are extracted for each dominant pulse; a detailed description of the MOCAIP algorithm can be found in Hu et al. (30).

There were 2,785 dominant ICP pulses analyzed for the patient population. The results had a mean and standard deviation of 397.9 ± 95.8 dominant pulses per patient, with a range from 209 to 503 pulses.

For the individual dominant pulses, we focused on nine temporal metrics and two common amplitude metrics. The small subset of metrics were chosen to specifically investigate the relationship of the three characteristic peaks where the amplitude metrics (mean ICP and

ICP pulse pressure wave amplitude) are commonly used as the gold-standard measurement in ICP monitoring/analysis. For the temporal metrics, we investigated three physiological parameters related to each of the three characteristic pulses, giving a total of nine metrics. The three physiological parameters are the rising time of the leading edge (the time between the preceding valley and subsequent peak), the time of the falling edge (the time from the peak to the following valley), and, finally, the time between subsequent valley points (representing the width of the peak). Mean ICP (mICP) and the ICP pulse pressure amplitude (waveAmp) were chosen as the amplitude metrics for this study.

Following calculation of the metrics sets (PC-MRI and ICP), Spearman’s rank correlation coefficient (r) was used to quantify the dependencies of the ICP metrics and the ASV. Each patient’s overnight ICP data contained several dominant pulses produced by the MOCAP algorithm. Therefore, for the statistical comparison, the median values of the overnight metric (nine temporal and two amplitude metrics) were compared with the ASV imaging data. The overnight section of ICP data was selected based on relatively low noise compared with the day time hours and patient position (supine); this allowed us to remove any subjectivity in selecting specific segments of ICP and has been used in several studies (9, 17, 32). Finally, to account for the multiple comparisons used in this study, the statistical level of 0.05 was altered based on the Bonferroni correction. All statistical tests were performed in MATLAB 7.5 R2007b.

RESULTS

The ASV for the seven patients had a mean ± SD of 0.156 ± 0.043 ml. These values compare well with previously published ASV for NPH patients (1, 5). The age of the patients did not show any significant relationship for either the ASV or ICP metrics.

The correlation values between the ICP temporal metrics and PC-MRI ASV metrics are shown in Table 2, with significant values marked with an asterisk for P values of <0.05 corrected for multiple comparisons. Of the nine temporal metrics correlated with the ASV, only the width of P2 (ICP-Wi2) was significantly correlated (P = 0.0025); however, the rising edge of P2 (ICP-Wi2') only trended toward significance (P = 0.0068) based off multiple comparisons. Scatter plots of selected metrics (peak widths) are shown in Fig. 2, A–C, along with a linear fit of the variables and a 95% prediction interval. Also shown in Fig. 2D is a sample ICP pulse pressure waveform that depicts the definitions of the studied temporal metrics. Both the ICP pulse pressure amplitude (P = 0.023) and the mean ICP (P = 0.6445) failed to reach the corrected significance level (Fig. 3).

DISCUSSION

Our study found a significant positive correlation between the width of the second peak of an ICP pulse (ICP-Wi2) and the aqueduct stroke volume (ASV) in patients with probable NPH. This was a rather specific finding in that neither mean ICP, the pulse amplitude (waveAmp), nor the width of the other two peaks achieved a significant correlation with ASV. This correlation supports our hypothesis that the P2 peak morphology would be more closely tied to measures of aqueductal CSF flow than the other ICP peaks (P1 and P3).

As shown in Table 2, the significant correlation with ASV was exclusive to the P2 region of ICP. Qualitatively the different characteristics of the three regions of an ICP pulse can be seen in Fig. 4 where two sets of ICP pulse pressure waveforms (Fig. 4, C and D) are shown for relatively different ASV (Fig. 4B). Furthermore, the waveforms in Fig. 4, C and D, have equal mean ICP values (for both sets of waveforms) since it has been well established that mean ICP impacts ICP waveform morphology (24). One interpretation for this result is that the driving pressure required to displace an increased CSF volume through the aqueduct is related to the second peak of the ICP pulse. As noted previously, early physiological studies suggested that the first peak of ICP pulse primarily reflects the pulsations of large intracranial conductive arteries and that the third peak of an ICP pulse mainly reflects venous pulsation (2, 24). We of course can only speculate as to what factors contribute to the P2 morphology. The high correlation with ASV might suggest that capillary-phase brain expansion, as proposed by Greitz (21), is a likely dominant component. There are other possible drivers of ventricular CSF pulsatile movement, including pulsations in the ventricular choroid plexus (6).

Physiologically, the relationship between the width of P2 and the ASV is likely related to the finite time required for capillary bed expansion after each heart beat. Since the early
1940s, CSF flow dynamics have been tied to arterial blood flow into the cranial vault (35). Greitz et al. expanded on this idea using phase-contrast MRI, where they showed distinct brain expansion and retractions phases with an estimation of CSF flow in the aqueduct delayed several hundred milliseconds after the ECG R-wave due to the capillary bed expansion (20). In our study, the PC-MRI measurement was made in the cerebral aqueduct. Incorporating the relationship between capillary bed expansion and CSF movement through the aqueduct, we believe that the proposed link between the temporal metric of ICP and ASV is justifiable based on the capillary filling time. Moreover, we believe that the temporal correlations of ICP do not end with the filling of the capillary bed, as suggested by this study. We speculate a different temporal ICP metric may be correlated if a pulsatility measurement (flow stroke volume, etc.) was made in another location (foramen of magnum, prepontine cistern, etc.). Finally, from a technical standpoint, studies investigating ICP pulse pressure temporal metrics are rare; Eide et al. reported no significant difference between NPH shunt responders and nonresponders for mean ICP rise time (time from diastolic to the systolic peak) (17). However, to our knowledge, the temporal features of the subpeaks of the ICP pulse have not been studied. MOCAIP provides the ability to reliably study subpeak temporal metrics and thus addresses an unmet need in the investigation of ICP waveform morphology investigation.

The existence of correlation between a specific local feature of ICP pulses and ASV indicates that the global mean value of ICP and the characteristics of the three individual regions of an ICP pulse may reflect different aspects of the CSF dynamics and can provide complementary information. Such a finding therefore challenges the current paradigm of monitoring only mean ICP while ignoring the shape of an ICP pulse (16). Eide’s recent clinical studies have shown that ICP amplitude can be potentially more important to guide the management of hydrocephalus patients (14, 17) and subarachnoid hemorrhage patients (13) than mean ICP. The present work shows that temporal metrics, such as ICP-Wi2, may provide additional insights to CSF dynamics and play a role in managing patients with a wide variety of altered CSF dynamics.

A few tangentially related studies have shown relationships between ICP and CSF dynamics, although not directly linking ICP morphological metrics and CSF dynamics. Alperin et al. utilized the characteristic pressure volume curve to estimate ICP noninvasively using MRI to quantify CSF and blood flow into the cranial vault (3). Although this study did not address ICP waveform morphology, it did suggest an association between the two measures of pulsatility investigated in our study. Another study investigated the efficacy of ASV for predicting outcome of shunt surgery in NPH, comparing ASV to lumbar CSF pressures before and during lumbar infusion study. The results showed no significant correlation between ASV and mean baseline lumbar pressure or ASV and mean plateau pressure. However, there was a correlation with both baseline and plateau pulse amplitude and ASV (31). Again, the aforementioned studies simply suggest a possible relationship between noninvasive measures of CSF pulsatility and invasive pressure measurements, which act as reasonable background for our results. A limitation of our study was the small sample size. In our study design, patients being evaluated for possible NPH were given the option to participate in research MRI study. Some
chose not to for personal reasons (including claustrophobia), whereas, for some, the MRI studies obtained were not analyzable due to technical reasons (such as malfunctioning ECG gating software). In one respect, this small number of subjects coupled with the multiple comparisons would challenge us more in achieving a significant P value when quantifying the correlation between metrics. We also acknowledge that there was a variable time lag between the ICP measurement and the time of PC-MRI imaging. However, acute changes of either ICP pulse morphology or CSF flow dynamics are unlikely in this patient population, and simultaneous measurements of invasive ICP morphology and CSF dynamics are not currently possible. It remains to be studied whether ICP-Wi2 can be a specific and sensitive metric to provide continuous surveillance of acute changes of the ASV.

In conclusion, in this study, we showed the width of the second peak of an ICP pulse wave is positively related to the volume of pulsatile CSF movement through the cerebral aqueduct. This finding is important because it helps our understanding of the specific ICP pulse wave morphological metrics studied in this work. Given the existing evidence that increased aqueductal CSF stroke volume is a marker of impaired CSF flow dynamics, ICP monitoring equipped with a metric of second peak width can thus offer continuous assessment of CSF dynamics change that mean ICP will fail to capture.
