Submitted 3 May 2013; accepted in final form 17 June 2013

Emhoff CW, Messonnier LA, Horning MA, Fattor JA, Carlson TJ, Brooks GA. Direct and indirect lactate oxidation in trained and untrained men. J Appl Physiol 115: 829–838, 2013. First published June 20, 2013; doi:10.1152/japplphysiol.00538.2013.—Lactate has been shown to be an important oxidative fuel. We aimed to quantify the total lactate oxidation rate (Rox) and its direct vs. indirect (glucose that is gluconeogenically derived from lactate and subsequently oxidized) components (mg·kg−1·min−1) during rest and exercise in humans. We also investigated the effects of endurance training, exercise intensity, and blood lactate concentration ([lactate]b) on direct and indirect lactate oxidation. Six untrained (UT) and six trained (T) men completed 60 min of constant load exercise at power outputs corresponding to their lactate threshold (LT). T subjects completed two additional 60-min sessions of constant load exercise at 10% below the LT workload (LT−10%), one of which included a lactate clamp (LC; LT−10%+LC). Rox was higher at LT in T [22.7 ± 2.9, 75% peak oxygen consumption (V̇O2peak)] compared with UT (13.4 ± 2.5, 68% V̇O2peak, P < 0.05). Increasing [lactate]b (LT−10%+LC, 67% V̇O2peak) significantly increased lactate Rox (27.9 ± 3.0) compared with its corresponding LT−10% control (15.9 ± 2.2, P < 0.05). Direct and indirect Rox increased significantly from rest to exercise, and their relative partitioning remained constant in all trials but differed between T and UT: direct oxidation comprised 75% of total lactate oxidation in UT and 90% in T, suggesting the presence of training-induced adaptations. Partitioning of total carbohydrate (CHO) use showed that subjects derived one-third of CHO energy from blood lactate, and exogenous lactate infusion increased lactate oxidation significantly, causing a glycogen-sparing effect in exercising muscle.

lactate oxidation; gluconeogenesis; glucose; muscle glycogen; exercise; training; stable isotope tracers

LACTATE IS NOW WIDELY RECOGNIZED as an important oxidative fuel (8, 12, 17, 27, 29, 32, 42, 58, 60) rather than a dead-end waste product of anaerobic metabolism. Under resting conditions, lactate uptake from the circulation occurs in various tissues, including but not exclusive to cardiac muscle (22, 41, 57, 80), skeletal muscle (8, 9, 21, 27, 33, 43, 68, 71, 72), and brain (51, 71) for oxidative metabolism, and liver and kidneys for gluconeogenesis (GNG) (7, 35, 52, 58, 66). Lactate has also been shown to contribute directly to glycogen synthesis in liver and indirectly in muscle (2-4, 14, 61). Previous measurements of lactate rates of disposal (Rd) and oxidation (Rox) in humans have used methods, including arterio-venous difference measurements (8, 19, 21, 77), infusion of isotope tracers (15, 41, 58–60, 64, 65, 76–78), and muscle biopsies (8, 19, 53), all of which have shown that during continuous exercise, most lactate disposal occurs via oxidation in working skeletal muscle. However, because lactate is the primary gluconeogenic precursor, availability of the presence of high levels of lactate in the circulation supports GNG and the production of glucose (7, 32, 35, 52, 58, 66), which may subsequently undergo oxidation. When circulating lactate enters cells for oxidative disposal, the route is considered to be “direct oxidation” of blood lactate. Conversely, when lactate is converted to glucose through hepatic or renal GNG, subsequent oxidation of the lactate-derived glucose monomer can be considered as “indirect oxidation” of the precursor lactate. Most studies using the methodologies described above either do not discriminate between or lack the means to measure these two routes of lactate oxidation simultaneously. Thus the present investigation aimed to quantify the direct and indirect lactate Rox during rest and exercise in humans and to investigate the individual and combined effects of endurance training, exercise intensity, and blood lactate concentration ([lactate]b) on their relative partitioning.

We hypothesized that endurance training increases direct lactate oxidation during exercise, whether determined at a given relative exercise intensity, as assessed by peak oxygen consumption (%V̇O2peak), or at the lactate threshold (LT). Characterized as the onset of rapid blood lactate accumulation, the LT was selected as the target exercise intensity because of its association with endurance exercise performance and its widespread use in the management of endurance training (28, 62, 74, 82). Furthermore, exercise training has been shown to exert a profound effect on the LT through whole-body adaptations, including an enhanced capacity for lactate clearance (8, 10, 32, 59, 75, 81). To test our hypothesis of a training-induced enhancement of lactate clearance via oxidation, we studied endurance-trained (T) and untrained (UT) men exercising at LT, and we used indirect calorimetry and stable isotope tracers to determine glucose and lactate fluxes and lactate Rox. As well, we incorporated a lactate clamp (LC) component, involving exogenous infusion, to test the hypothesis that an increase in blood lactate availability would increase direct lactate oxidation, sparing the use of other carbohydrate (CHO) sources, specifically, muscle glycogen and blood glucose.

METHODS

This manuscript presents results from a large investigation of lactate and glucose metabolism during exercise at the LT. Many details of methodology are reported separately (35, 63) but are repeated here for the convenience of the reader.

Subjects. Twelve healthy male subjects (six UT and six T), aged 19–33 yr, were recruited from the University of California, Berkeley, campus and the surrounding community by posted notices, word of mouth, and e-mail. UT subjects were healthy and recreationally active (V̇O2peak <50 ml·kg−1·min−1); T subjects were members of competitive cycling or triathlon teams, currently in the race phase of their training season (V̇O2peak >55 ml·kg−1·min−1). Subjects were in-
cluded in the study if they had a body mass index ≥18 and <26 kg/m², were nonsmokers, were diet and weight stable, had a forced expiratory volume in 1 s/forced vital capacity ratio ≥70%, and were injury/disease free, as determined by physical examination. This study was approved by the University of California, Berkeley, Committee for the Protection of Human Subjects (CPSH 2010-4-1300) and conformed to the standards set by the Declaration of Helsinki. All subjects gave written, informed consent before participation in the study.

**Preliminary testing.** Exercise tests were performed on an electronically braked leg-cycle ergometer (Monark Ergometrie 839E; Monark Exercise AB, Vansbro, Sweden) and were conducted at least 1 wk apart. Following interviews and screening, subjects performed two graded exercise tests to determine VO₂peak and LT. To determine VO₂peak, as per the American College of Sports Medicine Guidelines (7th edition), exercise power output (PO) started at 75 or 120 W and was increased by 25 or 30 W for the UT and T groups, respectively, every 3 min until volitional fatigue. Expired respiratory gases were monitored continuously throughout the test via an open-circuit, automated, indirect calorimetry system (TrueOne metabolic system; ParvoMedics, Sandy, UT) that was calibrated using room air and a certified calibration gas. Finger pricks drawing 10 µl blood were conducted at the end of each stage to measure [lactate]₀ via portable lactate analyzers (Lactate Plus; Nova Biomedical, Waltham, MA) and to approximate the PO eliciting the LT.

To determine LT, a second graded exercise test started at 50 W below the approximated LT PO and increased by 10 W every 3 min until volitional exhaustion. At the end of every stage, 1 ml blood was drawn from a warmed “arterialized” hand vein for enzymatic analysis of [lactate]₀, which increased slowly with exercise work rate until a certain PO. After this point, a rapid acceleration in blood lactate accumulation occurred. The LT was considered to be the last stage of the slow increase in [lactate]₀, before the rapid increase in lactate accumulation. This definition of the LT is termed by some as the second lactate turn point (47). For both graded exercise tests, heart rate was monitored continuously using a heart-rate monitor (Polar, Gays Mills, WI) and electrocardiography (Q750 ECG, Quinton Instrument Company, Seattle, WA); rating of perceived exertion (RPE) was recorded, according to the Borg scale (11); and blood pressure was measured at the middle of every stage by manual auscultation.

On a subsequent day, subjects performed 60 min of continuous exercise at the PO corresponding to their LT to ensure stabilization of [lactate]₀ over the entire duration of the exercise test. Every 10 min, finger pricks, drawing 10 µl blood, were conducted to measure [lactate]₀, and heart rate and RPE were monitored.

**Experimental design.** The study design consisted of four conditions using stable isotope tracers: one condition within the UT group and three conditions within the T group. UT subjects completed one isotope infusion trial, consisting of a 90-min rest period, followed by 60 min of continuous cycling at the LT. T subjects completed three isotope infusion trials, each consisting of a 90-min rest period, followed by 60 min of continuous leg-ergometer cycling under one of the following conditions: 1) PO eliciting the LT, 2) PO 10% below that eliciting the LT (LT−10%), and 3) LT−10% but with a LC (exogenous lactate infusion) to raise [lactate]₀ to the LT level (LT−10%+LC). The order of the last two conditions was randomized, and all exercise trials were conducted at least 1 wk apart. For the day before each trial, subjects were instructed to abstain from structured exercise or hard physical activity but to continue typical activities of daily living.

To evaluate the effects of training on metabolic responses, we compared UT and T groups exercising at the same [lactate]₀ but different absolute and relative intensities (UT-LT vs. T-LT); at the same relative intensity but different [lactate]₀ (UT-LT vs. T-LT−10%); and at the same relative intensity and [lactate]₀ (UT-LT vs. T-LT−10%+LC). Within the T group, we investigated the effects of exercise intensity given the same [lactate]₀ (LT vs. LT−10%+LC); the effects of [lactate]₀, given the same exercise intensity (LT−10% vs. LT−10%+LC); and the combined effects of [lactate]₀ and exercise intensity (LT vs. LT−10%).

**Dietary controls.** Three-day diet records were collected before the study to record subjects’ caloric intake and macronutrient composition (Diet Analysis Plus, version 6.1; ESHA Research, Salem, OR). Subjects also provided complete 24-h diet records of the day preceding each exercise session. Standardized diets (~50% CHO, 30% fat, 20% protein) were given the day before each exercise trial, including dinner and an evening snack as the last meal. Diets, consisting of an average of 2,400 and 3,200 kcal for the UT and T groups, respectively, were individualized and determined for each participant considering a physical-activity level (54) of 1.25 for UT and 1.48 for T, according to the current Dietary Reference Intake guidelines of the Institute of Medicine for Estimated Energy Requirement. Subjects came to the laboratory overnight fasted, and exercise commenced 2 h after consuming the evening snack. No food or beverages were allowed except water (ad libitum) until the end of the exercise session.

**Isotope tracer protocol.** Subjects reported to the laboratory on the morning of each isotope tracer trial, and expired respiratory gases were sampled for measurement of background ¹³CΟ₂ enrichment. A catheter was then placed into a warmed hand vein for arterialized blood sampling, and a background sample was collected. Through a second catheter placed in the antecubital vein of the contralateral arm, subjects received a primed, continuous infusion of [6,6-²H₂]glucose (D₂-glucose) and [3-¹³C]sodium-lactate (Sigma-Aldrich, St. Louis, MO). Isotopes were diluted in 0.9% sterile saline and were tested for pyrogenicity and sterility [School of Pharmacy, University of California, San Francisco (UCSF), CA] and passed through a 0.2-µm Millipore filter (Nalgene, Rochester, NY) before infusion. Priming boluses contained 250 mg D₂-glucose, 57.5 mg [3-¹³C]sodium-lactate, and 136 mg [¹³C]sodium-bicarbonate (Isotec; Sigma-Aldrich). Glucose and lactate tracers were then infused continuously for the 90-min rest period via a calibrated pump (Baxter Colleague 3CX; Baxter, Deerfield, IL) at 2.0 mg/min for glucose and 2.5 mg/min for lactate in all trials, with the exception of the LT−10%+LC trial that had a resting infusion rate of 7.5 mg/min for lactate. The LT−10%+LC trial also included infusion of an unlabeled lactate acid-sodium hydroxide mixture to target a specific [lactate]₀ during the rest period (see LC procedure). At the start of all exercise trials, tracer infusion rates were increased to 8 mg/min for glucose and 11.25 mg/min for lactate for the UT group and 10 mg/min for glucose and 15 mg/min for lactate for the T group and continued for 60 min of exercise.

**LC procedure.** In the LT−10%+LC trial, a LC procedure was performed, as described previously (65). An unlabeled lactate cocktail was prepared by mixing a 30% lactate acid solution (Sigma-Aldrich) in 2 N sodium hydroxide to a pH of 4.8 and subsequently tested for pyrogenicity and sterility at the UCSF School of Pharmacy. During the rest period, unlabeled lactate infusion began at 4.9 mg·kg⁻¹·min⁻¹ to raise [lactate]₀ to that obtained individually during the LT trial. Infusion rates were adjusted during rest and exercise to maintain the target [lactate]₀, as determined by a portable lactate analyzer.

**Blood and respiratory gas sampling.** Arterialized blood was drawn from a warmed hand vein for metabolite, isotopic enrichment (IE), and hormonal analyses at 0 (background), 60, 75, and 90 min of rest and 10, 20, 30, 40, 50, and 60 min of exercise. Hematocrit was also measured at each time point using a circular microcapillary tube reader (No. 2201; International Equipment, Needham Heights, MA). Blood for [glucose], [lactate], and IE determinations was deproteinized immediately with 8% perchloric acid, shaken, and placed on ice. All samples were centrifuged at 3,000 g for 18 min, and the supernatant was transferred to storage tubes and frozen at −80°C until analysis.

Respiratory gases were analyzed continuously via indirect calorimetry for 5 min before and coincident with blood sampling. These measurements were used for calculation of VO₂, carbon dioxide production (VCO₂), respiratory exchange ratio (RER), and minute
ventilation. Duplicate samples of expired air were collected in 10-ml evacuated containers for \(^{13}\)CO\(_2\) IE determinations. Careful attention was placed on flushing the line and sampling expired CO\(_2\) at the same time as blood was drawn for glucose and lactate IE. Heart rate, blood pressure, and RPE measurements were also recorded at the same frequency as blood and breath sampling.

**Metabolite concentration and IE analyses.** Methods for the determination of [glucose] (35), [lactate] (63), and IEs have been described previously. Briefly, known amounts of uniformly labeled internal standards \([U-^{13}\text{C}]\)glucose and \([U-^{13}\text{C}]\)lactate were added to the supernatant samples, collected in 8% perchloric acid. Samples were then neutralized with 2 N KOH and transferred to ion exchange columns that were washed previously with double deionized water (ddH\(_2\)O) through a cation resin (Analytical Grade 50W-X8, 50–100 mesh H\(^+\) resin; Bio-Rad Laboratories, Hercules, CA) and with ddH\(_2\)O, followed by 2 N formic acid through an anion resin (Analytical Grade 1-X8, 100–200 mesh formate resin). Glucose was eluted first with ddH\(_2\)O, followed by elution of lactate through the anion column with 2 N formic acid. Subsequent glucose analyses and kinetics data are reported separately (35).

Lactate IE was determined by GC-MS (GC model 6890 series and MS model 5973N; Agilent Technologies, Santa Clara, CA) of the N-propylamide heptanfluorobutyrate derivative, where methanol was used for selected ion monitoring of mass:charge ratios 328 (unlabeled lactate), 329 (mass+1 isotope, [3-\(^{13}\)C]lactate), and 331 (mass+3 isotope, [U-\(^{13}\text{C}]\)lactate internal standard). Whole [lactate]\(_0\) was determined by abundance ratios of 328:331:333. Selected ion abundances were compared against external standard curves for calculation of concentration and IE.

Breath samples were analyzed via isotope ratio MS by Metabolic Solutions (Nashua, NH).

**Calculations.** For calculation of R\(_{ox}\), data from the last 30 min of rest (i.e., 60, 75, and 90 min) and the last 20 min of steady-rate exercise (i.e., 40, 50, and 60 min) were used. Lactate rates of appearance (R\(_{a}\)), R\(_{d}\), and metabolic clearance (MCR) are reported separately (63). Total lactate R\(_{ox}\) (mg·kg\(^{-1}\)·min\(^{-1}\)) was calculated from expired CO\(_2\) and IECO\(_2\) (85)

\[
\% \text{Lactate } R_d \text{ oxidized} = \frac{(IECO_2 \times VCO_2 \times 90.08)}{(F \times k \times 22.4)} \times 100
\]  

Total lactate R\(_{ox}\) = (Lactate R\(_{g}\) \times \% Lactate R\(_{d}\) oxidized) / 100

where IECO\(_2\) is the excess IE of expired \(^{13}\)CO\(_2\); VCO\(_2\) is in l/min; 90.08 is the molecular weight of [3-\(^{13}\)C]lactate; F is the [3-\(^{13}\)C]lactate infusion rate in mg·kg\(^{-1}\)·min\(^{-1}\); k is the correction factor for the retention of CO\(_2\) in body pools, as determined previously (46) to be 0.83 at rest and 1.0 during exercise; and 22.4 is the molar volume of CO\(_2\), a nonideal gas under standard temperature and pressure conditions.

Calculations for the rate of GNG from lactate (R\(_{g}\)mg; mg·kg\(^{-1}\)·min\(^{-1}\)) and glucose R\(_{d}\) (mg·kg\(^{-1}\)·min\(^{-1}\)) are reported separately (35). Indirect and direct R\(_{ox}\) (both in mg·kg\(^{-1}\)·min\(^{-1}\)) and glucose R\(_{ox}\) (mg·kg\(^{-1}\)·min\(^{-1}\)) were calculated

\[
\text{Indirect lactate } R_{ox} = R_{g} \times c
\]

\[
\text{Direct lactate } R_{ox} = \text{Total lactate } R_{ox} - \text{Indirect lactate } R_{ox}
\]

\[
\text{Glucose } R_{ox} = \text{Glucose } R_d \times c
\]

where c is relative glucose oxidation, as determined previously to be 0.25 at rest, 0.20 at rest with LC (65), and 0.80 during exercise, with and without LC (38, 39, 64, 65).

Because exogenous lactate infusion was not expected to affect lipid oxidation (23, 36), the overall CHO R\(_{ox}\) (mg·kg\(^{-1}\)·min\(^{-1}\)) was derived from the equation of Consolazio et al. (26), assuming negligible contribution of protein oxidation

\[
\text{CHO } R_{ox} = \frac{(4.55 \times VCO_2) - (3.21 \times V_2)}{m} \times 1000
\]

where \(VCO_2\) and \(V_2\) are in l/min; and \(m\) is the subject’s body mass in kg. The muscle glycogen R\(_{ox}\) (mg·kg\(^{-1}\)·min\(^{-1}\)) was calculated as the remaining CHO use after glucose and lactate

Muscle glycogen R\(_{ox}\) = CHO R\(_{ox}\) - Glucose R\(_{ox}\)

Because indirect lactate R\(_{ox}\) is included in the measurement for glucose R\(_{ox}\), only direct lactate R\(_{ox}\) was used for the determination of glycogen R\(_{ox}\). Lipid R\(_{ox}\) (g/min) was also calculated from the equation of Consolazio et al. (26), assuming negligible contribution of protein oxidation

\[
\text{Lipid } R_{ox} = (1.67 \times V_2) - (1.67 \times VCO_2)
\]

From oxidation values, we estimated further caloric expenditures (kcal/min) from lactate, glucose, muscle glycogen, and lipid using 4.2 and 9.5 for kilocalories, provided/gram of oxidized CHO and lipid, respectively.

**Statistical analyses.** Significance of differences in subject characteristics between UT and T groups was analyzed using an unpaired Student’s t-test. Differences in metabolic parameters between the UT and the three T conditions within rest and exercise were analyzed using a one-way ANOVA. Analyses within the T conditions were done with repeated measures. Post hoc analyses were made using Fisher’s least significant difference multiple comparisons test. Differences from rest to exercise were analyzed using a paired Student’s t-test. Statistical significance was set at \(\alpha = 0.05\), and values are represented as means ± SE.

**RESULTS.**

Anthropometric and dietary data of UT and T subjects as well as cardioventilatory and hormonal responses to graded tests and isotope tracer trials are reported separately (35, 63). Glucose (35) and lactate (63) kinetics data, including R\(_{a}\), R\(_{d}\), and MCR, are also reported separately. Some previously presented results are repeated here for the convenience of the reader or when used for novel calculations.

IE of expired \(^{13}\)CO\(_2\). IEs of expired \(^{13}\)CO\(_2\), presented as atom percent excess (APE) over time (Fig. 1), was significantly higher in the LT–10%+LC trial compared with the LT and LT–10% trials in the T group at rest (\(P < 0.05\)). Greater \(^{13}\)CO\(_2\) during the LC protocol was consistent with the increased lactate tracer infusion rates that were three times higher in the LC protocol during the rest period than those during the non-LC trials. During exercise, APE of expired \(^{13}\)CO\(_2\) in the LT–10%+LC trial was significantly higher compared with the T-LT trial (\(P < 0.05\)), despite equal [lactate]\(_b\) (Table 1) and tracer infusion rates. During the transition from rest to exercise, the increase in tracer infusion rate closely matched the increase in metabolic rate, as a slight, although significant, increase in \(^{13}\)CO\(_2\) APE was observed in all trials (\(P < 0.05\)), except for the T-LT trial (\(P = 0.07\)), corroborating an increased flux and metabolism of endogenous lactate in T subjects exercising at the LT.

Lactate disposal and its partitioning between oxidation and GNG. At rest, lactate R\(_{d}\) were not different across non-LC resting conditions in both UT and T groups (Table 1), whereas exogenous lactate infusion raised lactate R\(_{d}\) nearly threefold (63). In non-LC trials, the percentage of lactate R\(_{d}\) oxidized was ~45% (Table 1). Within the T group, the increase in
disposal with LC did not correspond to an increase in oxidation (Fig. 2), as the percentage of lactate \( R_d \) oxidized in the LT-10%+LC trial was only one-half of the percentage in the non-LC trials (Table 1; \( P < 0.05 \)). During rest, 50.4 ± 10.6\% of lactate \( R_d \) in the UT group supported glucose production, whereas in the non-LC trials of the T group, approximately 20–23\% of lactate \( R_d \) appeared as glucose (Table 1; \( P < 0.05 \)). Lactate conversion to glucose was only 6.2 ± 1.4\% of lactate \( R_d \) in the LT-10%+LC trial, where \([\text{lactate}]_b\) was four times higher than in the non-LC conditions (\( P < 0.05 \)).

During the transition from rest to exercise, lactate \( R_d \) and percentage of lactate \( R_d \) oxidized significantly increased in all trials (Table 1; \( P < 0.05 \)). During exercise at LT, lactate \( R_d \) was 60\% greater (\( P < 0.05 \)) in the T group (75\% \( \dot{V}O_{2\text{peak}} \)) compared with the UT group (68\% \( \dot{V}O_{2\text{peak}} \)), despite no significant difference in [lactate]\(_b\). When T subjects exercised at LT-10\% (67\% \( \dot{V}O_{2\text{peak}} \)), lactate \( R_d \) was not different than UT. However, lactate \( R_d \) increased by nearly 60\% when exogenous lactate infusion raised [lactate]\(_b\) to similar levels as in UT, exercising at the same relative work rate (\( P < 0.05 \)). In both UT and T groups, exercising at ~67\% \( \dot{V}O_{2\text{peak}} \), ~89\% of lactate \( R_d \) was oxidized, which was lower than the LT (93.5 ± 1.2\% and LT-10%+LC trials in T (97.6 ± 2.3\%), although these differences were significant only compared with the UT group (\( P < 0.05 \)). Similar to resting conditions, the UT group demonstrated a greater reliance on GNG for lactate removal during exercise, where 25.7 ± 6.4\% of lactate \( R_d \) appeared as glucose. Only ~9\% of lactate \( R_d \) supported glucose production in the non-LC trials of the T group and 15.9 ± 3.7\% in the LT-10%+LC trial.

Lactate oxidation and its partitioning between direct and indirect oxidation. During rest, \( R_{ox} \) were similar across all non-LC trials (Fig. 2A). Absolute partitioning of direct and indirect lactate \( R_{ox} \) showed that exogenous lactate infusion during the rest period significantly increased direct and decreased indirect lactate \( R_{ox} \) compared with those of the UT group (\( P < 0.05 \)).

There was a significant increase in lactate \( R_{ox} \) in the transition from rest to exercise in all four trials (Fig. 2A). Total lactate \( R_{ox} \) was proportional to relative intensity during exercise, with the exception of the LT-10%+LC trial, where total lactate \( R_{ox} \) was augmented by 75\% during exercise (27.9 ± 3.0 mg kg\(^{-1}\) min\(^{-1} \)) compared with its corresponding LT-10\% control (15.9 ± 2.2 mg kg\(^{-1}\) min\(^{-1} \), \( P < 0.05 \)). At LT, total lactate \( R_{ox} \) was 70\% higher in the T group (22.7 ± 2.9 mg kg\(^{-1}\) min\(^{-1} \), 75\% \( \dot{V}O_{2\text{peak}} \)) compared with the UT group (13.4 ± 2.5 mg kg\(^{-1}\) min\(^{-1} \), 68\% \( \dot{V}O_{2\text{peak}} \), \( P < 0.05 \)). During exercise, absolute direct \( R_{ox} \) was significantly higher in the LT and LT-10%+LC trials of the T group compared with the other two trials (\( P < 0.05 \)). Exogenous lactate infusion also significantly increased indirect \( R_{ox} \) compared with the non-LC trials of the T group (\( P < 0.05 \)).

Relative partitioning of direct and indirect lactate \( R_{ox} \) (Fig. 2B) showed a significant training effect that increased direct lactate oxidation from ~75\% of total lactate \( R_{ox} \) in the UT group to ~90\% in the T group non-LC trials (\( P < 0.05 \)) during both rest and exercise. This relative partitioning was consistent regardless of activity level. At rest, LC did not alter direct and indirect lactate oxidation partitioning compared with the other T trials. During exercise, LC resulted in relative partitioning that was intermediate between the UT and non-LC T trials.

When represented as a percentage of lactate disposal, we estimated that at rest, 33–40\% of lactate \( R_d \) underwent direct oxidation in UT and non-LC T trials (Table 1). This partitioning was decreased significantly by exogenous lactate infusion,

Values for Lactate \( R_d \) and % Lactate \( R_d \) to glucose via GNG are from Messonnier et al. (63) and Emhoff et al. (35), respectively.
where only 22.4 ± 3.6% of lactate $R_d$ was oxidized directly in the LT−10%+LC trial. During the transition from rest to exercise, the percentage of lactate $R_d$ oxidized directly more than doubled, increasing significantly to 68.2 ± 4.9% in UT and 82–87% in T trials ($P < 0.05$). Differences between groups regarding the indirect lactate oxidation proportion during exercise almost mirrored that of direct oxidation; i.e., 20.5 ± 5.1% of lactate $R_d$ was oxidized indirectly in the UT group, exercising at LT, whereas 7–13% of lactate $R_d$ was oxidized indirectly in the exercise trials of the T group.

Partitioning of CHO oxidation. Determined by pulmonary gas exchange, total CHO $R_{ox}$ were slightly higher in the T group than that in the UT group during rest (Fig. 3A; $P < 0.05$). There was a significant increase in total CHO $R_{ox}$ in the transition from rest to exercise in all four trials ($P < 0.05$). Proportional to absolute workload during exercise, total CHO $R_{ox}$ in the T-LT trial was significantly higher than those in the other trials, and total CHO $R_{ox}$ in the T trials were higher than the UT trials ($P < 0.05$). Absolute partitioning of CHO $R_{ox}$ showed that glucose $R_{ox}$ was not different across trials, with the exception of LT−10%+LC, where exogenous lactate infusion increased glucose oxidation slightly compared with its corresponding LT−10% control (7.0 ± 0.7 mg·kg$^{-1}$·min$^{-1}$ vs. 6.0 ± 0.7 mg·kg$^{-1}$·min$^{-1}$, $P < 0.05$). Determined as the remaining CHO use next to glucose and direct lactate oxidation, muscle glycogen $R_{ox}$ was significantly higher ($P < 0.05$) during exercise in the T-LT (26.4 ± 3.7 mg·kg$^{-1}$·min$^{-1}$) and T-LT−10% (22.9 ± 1.7 mg·kg$^{-1}$·min$^{-1}$) trials compared with the UT-LT (14.2 ± 3.2 mg·kg$^{-1}$·min$^{-1}$) and T-LT−10%+LC (11.9 ± 2.3 mg·kg$^{-1}$·min$^{-1}$) trials.

Relative partitioning of CHO oxidation (Fig. 3B) showed that the T group had a lower contribution from blood glucose to CHO metabolism compared with the UT group (−17% vs. 36% at rest; −13% vs. 22% during exercise, $P < 0.05$). The provision of exogenous lactate in the LT−10%+LC trial decreased the reliance on blood glucose at rest (12.5 ± 3.3% vs. 18.2 ± 3.7%, $P < 0.05$) but increased glucose use during

**Fig. 2.** Steady-state rates of lactate oxidation ($R_{ox}$), partitioned into direct and indirect lactate oxidation in absolute (A) and relative (B) terms. Values are means ± SE, $n = 6$, for UT and T groups. ^Significantly different from rest within condition ($P < 0.05$); *significantly different from UT ($P < 0.05$); £significantly different from T-LT ($P < 0.05$); †significantly different from T−10% ($P < 0.05$).

**Fig. 3.** Steady-state carbohydrate (CHO) $R_{ox}$, partitioned into lactate, glucose, and muscle glycogen oxidation in absolute (A) and relative (B) terms. Values are means ± SE, $n = 6$, for UT and T groups. *Significantly different from rest within condition ($P < 0.05$); †significantly different from UT ($P < 0.05$); £significantly different from T-LT ($P < 0.05$); †significantly different from T−10% ($P < 0.05$).
exercise at 67% \( \dot{V}_\text{O}_2\text{peak} \) (16.4 \( \pm \) 1.8% vs. 13.9 \( \pm \) 1.7%, \( P < 0.05 \)). The relative contribution of direct lactate oxidation to total CHO metabolism was augmented significantly as a result of LC during rest (43.0 \( \pm \) 7.1% vs. 28.6 \( \pm \) 5.3%, \( P < 0.05 \)) and exercise (55.8 \( \pm \) 4.7% vs. 32.9 \( \pm \) 2.9%, \( P < 0.05 \)) compared with its corresponding LT—10% control. Due to the combined increases in direct lactate and glucose oxidation in the exercise LT—10% + LC trial, relative muscle glycogen use was decreased significantly compared with the non-LC trials in the T group (\( P < 0.05 \)).

**Caloric expenditure from CHO and lipids.** Resting metabolic rate in both UT and T groups was 1.8 kcal/min (Table 2), where lipid accounted for approximately 47–69% of total caloric expenditure (not significantly across trials). During exercise, total caloric expenditure was proportional to absolute workload, but percentage of lipid contribution was inversely proportional to relative exercise intensity, accounting for \( \sim 22\% \) of total caloric expenditure in UT and T groups, exercising at 67% \( \dot{V}_\text{O}_2\text{peak} \). In the T-LT trial (75% \( \dot{V}_\text{O}_2\text{peak} \), lipid accounted for only 16% of total caloric expenditure, although these differences did not achieve significance.

**DISCUSSION**

In this investigation, we examined the individual and combined effects of endurance training, exercise intensity, and [lactate]_{\text{in}} on lactate \( R_{\text{ox}} \) during exercise, at and just below the LT. Our main findings support the hypotheses that endurance training increases the capacity for lactate oxidation; in particular, the relative contribution of direct lactate oxidation to total lactate oxidation is increased, regardless of whether subjects are resting or exercising. During exercise, an increase in [lactate]_{\text{in}} via exogenous infusion increases lactate oxidation substantially and glucose oxidation slightly, resulting in significant sparing of muscle glycogen during exercise compared with its corresponding control.

In Fig. 4, we summarize our view of the relationship between lactate and glucose turnover in the blood. Lactate ap-

Values are means \( \pm \) s.e., \( n = 6 \), for untrained and trained groups. Percentages are relative substrate contribution to total caloric expenditure. Statistical symbols are for absolute caloric expenditure values: \( * \) significantly different from rest within condition (\( P < 0.05 \)); \( \dagger \) significantly different from trained LT (\( P < 0.05 \)); \( \ddagger \) significantly different from untrained (\( P < 0.05 \)); \( § \) significantly different from trained LT—10% (\( P < 0.05 \)).
pearance is shown to stem primarily from muscle glycogenolysis and to a lesser extent, glycolysis of blood glucose. Disposal of lactate includes GNG and direct oxidation, and muscle glycogen synthesis has a minor role. Lactate that enters GNG can support hepatic glycogen synthesis or glucose production, which is also dependent on hepatic glycogenolysis. Disposal of glucose includes oxidation and muscle or hepatic glycogen synthesis. A small portion of glucose disposal also re-enters the blood lactate pool. In this manuscript, we highlight the distinction between direct and indirect lactate oxidation, where the latter consists of lactate supporting glucose production and then undergoing oxidation as glucose.

**Direct and indirect lactate oxidation.** Measurements of whole-body lactate oxidation have been reported previously in laboratory mammals (16, 31, 37, 52) and humans (15, 58–60, 64, 65, 76–78). However, to our knowledge, the present investigation is the first to provide estimates of direct and indirect partitioning of lactate oxidation in resting and exercising humans (Fig. 2). Whereas absolute direct and indirect R_mox increase significantly from rest to exercise, their relative partitioning remains approximately constant, regardless of activity level within the UT and T groups. Direct oxidation remains the primary route of removal, comprising 75% of total lactate oxidation in the UT group and increasing up to 90% in the T group. Reciprocally, indirect lactate oxidation was significantly lower in T than in UT.

It is well established that splanchnic blood flow is inversely related to exercise intensity (1, 70), possibly limiting GNG at high exercise intensities (58, 83). In addition to local blood flow, [lactate]_b determines precursor supply to the liver and therefore, GNG. Despite higher PO (LT and LT−10% trials) and/or lower [lactate]_b (LT−10% trial), T subjects did not exhibit significantly different GNG rates than UT (35). This result indicates that endurance training has enhancing effects on GNG capacity (7, 35). Despite this training-attributed adaptation (i.e., similar GNG in T and UT during exercise at or close to LT), relative contribution of direct and indirect lactate oxidation was, respectively, higher and lower in T than in UT. These findings can be interpreted to mean that in T subjects, lactate is a preferred substrate over glucose (Fig. 3). Furthermore, the fact that a greater contribution of direct lactate oxidation was observed in the T group under resting conditions with and without LC suggests that blood flow distribution and precursor concentration were unlikely to have been major components in the preferential, direct use of lactate observed in the present investigation. Rather, there may be underlying training-induced adaptations that allow direct oxidation of lactate to occur, such as expansion of the apparatus described in the intercellular and intracellular lactate shuttles (12, 29). Indeed, endurance training has been shown to increase expression of sarcomemal and mitochondrial monocarboxylate transporter (MCT1) and sarcomemal MCT4 (34), facilitating the uptake of circulating lactate and intramuscular lactate exchange and oxidation.

The intracellular lactate shuttle hypothesis (12) suggests that oxidation begins in the mitochondrial intermembrane space, where lactate is converted to pyruvate via a postulated mitochondrial lactate oxidation complex (mLOC) of MCT1, lactate dehydrogenase (LDH), cytochrome oxidase (COX) (20), and CD147 (44, 45). Select colocalization of these putative mLOC components on the inner mitochondrial membrane has been shown using confocal laser-scanning microscopy in skeletal myocytes (44), cardiac myocytes (55), rat neurons (45), and other cells (84). Cellular locations of MCT1 and succinate dehydrogenase have also been reported to match (40), further linking MCT1 to the mitochondrial reticulum. Moreover, strong associations found among mitochondrial MCT1, CD147, LDH, and COX were not replicated by coprecipitation of complex I NADH dehydrogenase, suggesting a specific coupling with complex IV during mitochondrial electron transport (44). Most recently, a human biopsy study demonstrated that not only are skeletal muscle mitochondria capable of using lactate for mitochondrial respiration, but also, the conversion of lactate to pyruvate in the intermembrane space supports the existence of a functional mLOC (53). Therefore, as repeated muscle contraction during long-term training stimulates biogenesis of the mitochondrial reticulum, including a proportional increase in mitochondrial enzymes (5, 48–50, 56), the presence of a mLOC provides a plausible mechanism by which endurance training increases the capacity to clear and oxidize lactate directly, regardless of activity level.

Because increasing [lactate]_b via a LC provides substrate for both oxidation and GNG, LC did not significantly alter the relative partitioning of direct and indirect lactate oxidation in overnight-fasted subjects under resting conditions. Conversely, during exercise at LT−10% (67% VO2peak), direct and indirect R_mox were increased by 70% and 160%, respectively, with LC, suggesting that GNG may exhibit a greater reliance on substrate availability.

**Lactate, glucose, and muscle glycogen oxidation.** Total CHO oxidation is the summed use of blood lactate, blood glucose, and muscle glycogen. In our estimates, total CHO oxidation increases proportionally to exercise workload (Fig. 3A). Interestingly, whereas exercise intensity plays little or no significant role in the partitioning of CHO use among blood lactate, blood glucose, and muscle glycogen, training status and [lactate]_b have much greater impacts on this partitioning.

In the non-LC trials, UT and T groups obtain approximately 30–40% of CHO-derived energy from blood lactate at rest and during exercise (Fig. 3B). Since lactate production during exercise is predominantly a result of muscle glycogenolysis (73), the high lactate R_mox observed during exercise in this study suggest that lactate is shuttled from glycolytic cells to oxidative cells, well-described as the cell–cell lactate shuttle (12, 13). Evidently, this exchange of CHO fuel across tissue beds plays a substantial role under resting conditions as well. Blood glucose is a minor source of CHO energy in the T group, comprising <20% of CHO oxidation at rest and <15% during exercise. Consistent with other training studies investigating glucose metabolism in humans (6, 18, 24, 38, 39, 65, 69, 86), the UT group exhibits significantly greater reliance on blood glucose turnover, comprising over 35% of CHO oxidation at rest and 22% during exercise. Glycogen storage capacity is known to be greater after training (30, 67, 79), thus providing a plausible explanation for the greater contribution to total CHO oxidation in the T group at rest. However, during exercise, muscle glycogen use contributes to approximately 50–55% of CHO oxidation in UT and T groups in the non-LC trials. It is important to note that R_mox of muscle glycogen in the present study are specific to stores oxidized directly within the same muscle. Whole-body muscle glycogen oxidation, including the secondary glycogen use via lactate production, circu-
loration, and subsequent oxidation, may show a significant increase after training as well. However, further studies are required to quantify the shuttling of CHO fuel accurately from one tissue bed to another.

The effect of LC on blood glucose use is not well understood. Miller et al. (64) found that glucose R_{ox} was unaffected at rest and depressed significantly, due to LC in UT individuals, exercising at 55% VO_{2peak}. However, the present investigation found that estimated glucose R_{ox} was depressed during rest and slightly, yet significantly, augmented during exercise at 67% VO_{2peak} in highly trained individuals. It is plausible that the discrepancy in lactate and glucose interactions between studies may be due to differences in training state or exercise intensity—a question that warrants further investigation. Despite the differences in glucose metabolism, it is generally hypothesized that lactate oxidation is augmented by LC, likely by a concentration gradient-driven increase in facilitated diffusion across the plasma membrane. In this investigation, direct lactate oxidation has a tendency to increase at rest (P = 0.09) and is increased significantly during exercise (P < 0.05) when [lactate]_{b} is raised due to LC. As a result of the above-mentioned increases in glucose and lactate R_{ox}, a significant decrease in glycogen use within exercising muscle is observed during exercise at 67% VO_{2peak} with LC (P < 0.05). This sparing of muscle glycogen is primarily due to the near-doubling of lactate oxidation when [lactate]_{b} is increased by a similar proportion via exogenous infusion, suggesting that lactate may be a preferred fuel to delay depletion of glycogen stores within the exercising muscle.

**Limitations.** In the present study, we infused a ^{13}C-lactate tracer to measure lactate oxidation, and therefore, it was not possible to know glucose oxidation from simultaneous infusion of ^{13}C-glucose. Instead, blood glucose R_{ox} are derived from measured R_{d} and assumptions based on turnover studies previously conducted in humans using ^{13}C-glucose tracer infusion and subsequent IEs of expired ^{13}CO_{2}. We assume that 25% of glucose R_{d} is oxidized at rest (20% during LC) (65) and 80% during exercise, with or without LC (38, 39, 64, 65). Because the percentages of glucose oxidation have been reproducible within and across studies in our laboratory and because our tracer-measured flux rates agree with results of others (24, 25), we consider our glucose R_{ox} to be reasonable estimates within the physiological range. Similarly, muscle glycogen R_{ox} are estimated to be the remaining CHO oxidation next to glucose and lactate and are therefore subject to similar constraints.

During the LT−10%+LC resting condition, infusion of unlabeled lactate significantly increases lactate R_{d} but not lactate-derived glucose production (35), indicating that the increase in lactate disposal may support hepatic glycogen synthesis at rest. Those observations suggest a possibility for preloading of a lactate tracer into hepatic glycogen during the 90-min rest period of the LT−10%+LC trial. If the LC procedure resulted in hepatic glycogen preloading, then our measurements of lactate-derived glucose production and as well, indirect R_{ox} are overestimated during exercise. However, that error would further support our conclusion about a training-induced increase in direct vs. indirect lactate oxidation partitioning.

The infusion of exogenous lactate also introduces a CHO energy source in overnight-fasted subjects. On average, the LC procedure delivered 1.5 kcal/min during rest and 1.0 kcal/min during exercise. Although negligible during exercise, lactate infusion during rest may have altered the fasted state of the subjects. However, aside from the aforementioned effects on lactate and glucose oxidation, the infusion of exogenous lactate did not appear to affect total caloric expenditure or lipid use (Table 2).

Whereas we discuss the effects of endurance training, exercise intensity, and [lactate]_{b} on lactate oxidation partitioning at and just below the LT, our study used a cross-sectional design of UT and T individuals. Since this study did not use a training intervention, the data are emphasized to represent observed differences between the UT and T populations.

**Summary and conclusions.** We used stable isotope tracers and pulmonary gas-exchange measurements to determine whole-body partitioning of direct and indirect lactate oxidation in UT and T men during steady-state exercise, at and just below the LT. Additionally, we incorporated a LC component to examine the effect of exogenous lactate infusion on this partitioning. From these experiments, we conclude that endurance training and blood lactate availability provide optimal conditions for increasing direct lactate oxidation. In T individuals, the higher direct oxidative disposal of lactate, relative to its indirect oxidation, occurs both at rest and during exercise, suggesting training-induced adaptations on lactate oxidation that are independent of exercise parameters. From the standpoint of substrate use, the augmented capacity for direct lactate oxidation allows glycolytic tissues to support oxidative tissues by effectively redistributing carbohydrate fuel, as well as sparing glycogen within exercising muscle.
