Cao, Guohua, Barbara Shukitt-Hale, Paula C. Bickford, James A. Joseph, John McEwen, and Ronald L. Prior. Hyperoxia-induced changes in antioxidant capacity and the effect of dietary antioxidants. J. Appl. Physiol. 86(6): 1817–1822, 1999.—We investigated, by measuring oxygen radical absorbance capacity (ORAC), whether hyperoxia causes alterations in antioxidant status and whether these alterations could be modulated by dietary antioxidants. Rats were fed for 8 wk a control diet or a control diet supplemented with vitamin E (500 IU/kg) or with aqueous extracts (ORAC: 1.36 mmol Trolox equivalents/kg) from blueberries or spinach and then were exposed to air or >99% O2 for 48 h. Although the constituents of the extracts were not extensively characterized, HPLC indicated that blueberry extract was particularly rich in anthocyanins, and the spinach extract did not contain any anthocyanins. The ORAC was determined in samples without proteins [serum treated with perchloric acid (PCA); ORACPCA] and with proteins (ORACPCA). Hyperoxia induced a decrease in serum protein concentration, an increase in serum ORACPCA, decreases in lung ORACPCA and ORACPCA, and an equilibration of proteins and ORACPCA between serum and pleural effusion. These alterations suggested a redistribution of antioxidants between tissues and an increase in capillary permeability during hyperoxia. Only the blueberry extract was effective in alleviating the hyperoxia-induced redistribution of antioxidants between tissues.

Oxygen radical absorbance capacity; α-tocopherol; spinach; blueberry

 hypersorxia is thought to increase the production of reactive oxygen species (ROS) and disrupt the antioxidant defense mechanisms (23). Under basal conditions, ROS are generated during various cellular processes, but are counteracted by well-integrated antioxidant systems, which include enzymes such as superoxide dismutase, catalase, and glutathione peroxidase; macromolecules such as albumin, ceruloplasmin, and ferritin; and an array of low-molecular-weight (LMW) antioxidants, including ascorbic acid, α-tocopherol (vitamin E), β-carotene, reduced glutathione (GSH), uric acid, and bilirubin.

Previous studies showed that, with hyperoxia, oxygen radical production increased in rat lung slices, mitochondria (15), and homogenates (16) and in sheep pulmonary endothelial cells (43). An increased lipid peroxidation was reported in rat brain, lung, and kidney during hyperoxia by measuring fluorescent chromolipids (1). In general, the exposure of animals to hyperoxia results in a significant increase in pulmonary levels of superoxide dismutase, catalase, and glutathione peroxidase (12, 22, 27, 37), although a recent report does not support this conclusion (5).

However, in contrast to the large number of studies related to the adaptive responses of antioxidant enzymes to hyperoxia, studies on the effects of hyperoxia on nonenzymatic individual antioxidants are not as prevalent. Additionally, the responses to hyperoxia of these nonenzymatic antioxidants are somewhat inconsistent and not well explained, and the effect of hyperoxia on the total nonenzymatic antioxidant capacity has not been investigated. With hyperoxia, ascorbate decreased and dehydroascorbate increased in lung, whereas both ascorbate and dehydroascorbate increased in plasma (35); lung GSH decreased in old rats (5) but increased in neonatal and young rats (5, 26); and lung oxidized glutathione disulfide (GSSG) and the GSSG/GSH ratio increased in one study (40) and yet remained unchanged in another (26). Hyperoxia did not influence plasma, brain, and lung vitamin E status in guinea pigs (25).

The nonenzymatic antioxidants, most of which have low molecular weights and are able to directly and efficiently quench free radicals, constitute an important aspect of the body’s antioxidant mechanism. The limited and inconsistent reports about the response of some individual nonenzymatic antioxidants, mainly ascorbic acid and glutathione, to hyperoxia are not surprising, since the nonenzymatic antioxidant system includes many components, and there are potential interactions among these components. This makes the measurement of individual antioxidants difficult and also less informative while the measurement of total antioxidant capacity becomes necessary and more important in many conditions. Our oxygen radical absorbance capacity (ORAC) assay (6, 11) is one of the tests recently developed to measure the total antioxidant capacities of biological samples. The main advantage of the ORAC assay over other similar methods is its application of the area-under-curve technique in the quantitation process, giving consideration to both inhibition time and inhibition percentage of free radical action by an analyzed antioxidant sample (7, 8, 11).
molar of oxygen in the serum and lung, suggesting a redistribution of antioxidants between tissues during hyperoxia. Dietary supplementation of a blueberry extract, which is rich in antioxidant anthocyanins, modulated these hyperoxia-induced alterations in the total antioxidant capacity.

MATERIALS AND METHODS

Reagents. R-phycocerythrin (lot 10H40582) from Porphyra tenera ("Nori") was purchased from Sigma Chemical (St. Louis, MO). The R-phycocerythrin lost >90% of its fluorescence within 30 min in the presence of 4 mM of 2,2'-azobis(2-amidinopropane) dihydrochloride, obtained from Waco Chemicals (Richmond, VA). 6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) was obtained from Aldrich Chemical (Milwaukee, WI).

Animals and diets. The use of animals was conducted in compliance with all applicable laws and regulations as well as the principles expressed in the National Institutes of Health’s Guide for the Care and Use of Laboratory Animals. Forty-eight male Fischer 344 rats (6 mo old) were purchased from Harlan Sprague-Dawley/NIA (Indianapolis, IN). After their arrival, rats were transferred to a barrier facility at the University of Colorado Health Science Center in Denver, CO. All rats were acclimatized for the first 2 wk and then given a control diet or a control diet supplemented with either 500 IU/kg vitamin E acetate, 0.85% spinach extract, or 2.5% blueberry extract. The rats were divided randomly into 4 groups of 12 rats each: Control, Vitamin E, Spinach, and Blueberry. Both spinach and blueberries have a high antioxidant capacity, as assessed by the ORAC assay (9, 32). The blueberry extract was particularly rich in antioxidant anthocyanins (1.143 g/kg or 42% of the total phenolics), whereas the spinach extract did not contain any anthocyanins (Fig. 1).

The ORAC assay has been used by different laboratories and has provided significant information regarding the antioxidant capacity of various biological samples, from pure compounds such as melatonin, dopamine, and flavonoids to complex matrices such as tea, fruits, vegetables, herbs, and animal tissues (7, 8). By using the ORAC assay in this rat study, we found that hyperoxia induced significant alterations in the total antioxidant capacity in serum and lung, suggesting a redistribution of antioxidants between tissues during hyperoxia. Dietary supplementation of a blueberry extract, which is rich in antioxidant anthocyanins, modulated these hyperoxia-induced alterations in the total antioxidant capacity.

1:1, vol/vol) and centrifuged at 4°C for 10 min. The supernatant was recovered for the ORAC (ORAC PCA) assay. Pleural effusion was measured for its volume and centrifuged at 4°C for 10 min. The supernatant was recovered and assayed by Tukey's honestly significant difference test using Systat software. Differences at P < 0.05 were considered significant.

RESULTS

The HPLC chromatograms shown in Fig. 1 for the blueberry and spinach extracts indicate that the blueberry extract is particularly rich in anthocyanins, whereas spinach extract does not contain any anthocyanins. Anthocyanins are characterized by two absorption peaks, which are at 280 and 520 nm, respectively. Other flavonoids have absorption peaks at 280 nm but not at 520 nm.

The weights of rats in each group increased by 6–8% after the feeding of the diets for 8 wk, with no significant differences observed between different diet groups.

Effects of diets and hypoxia on serum protein concentration and antioxidant capacity. The effects of diets and hypoxia on serum protein concentration and antioxidant capacity are shown in Table 2. Serum protein concentrations decreased significantly with hyperoxia in all animals except those receiving blueberry extract. Compared with the air-exposed controls, serum ORACPCATOT increased significantly in the air-exposed rats receiving blueberry or spinach extract but not in the air-exposed rats receiving vitamin E. Hyperoxia had no significant effect on the serum ORACPCATOT in any group, but it significantly increased serum ORACPCAPCA in all animals except those receiving blueberry extract. Serum ORACPCAPCA was not significantly affected by hyperoxia in the animals receiving blueberry extract.

Protein concentration, antioxidant capacity, and volume of the pleural effusion from the rats exposed to hyperoxia. The rats exposed to >99% oxygen for 48 h showed obvious lung edema and pleural effusion, two typical pathological changes seen in lung oxygen toxicity. There was no lung edema, and visible pleural effusion formed in the rats exposed to air for 48 h. As

Values are means ± SE. ORACPCATOT, oxygen radical absorbance capacity of untreated serum; ORACPCAPA, oxygen radical absorbance capacity of the serum nonprotein fraction treated with perchloric acid (PCA). There was no visible pleural effusion in rats exposed to air. See text for further description. *O₂ vs. air, P < 0.05; †Spinach or Blueberry vs. Control group, P < 0.05; ‡pleural effusion vs. serum, P < 0.05.
shown in Table 2, the protein concentrations and the ORAC\textsubscript{PCA} values of the pleural effusion were not significantly different from those of serum in the rats exposed to hyperoxia in the Control, Vitamin E, and Spinach groups. However, the protein concentration was significantly lower, and the ORAC\textsubscript{PCA} value was significantly higher, in the pleural effusion compared with the serum in the rats receiving blueberry extract. The pleural effusion ORAC\textsubscript{tot} was significantly lower than serum ORAC\textsubscript{tot} in all the rats exposed to hyperoxia. However, the volume of pleural effusion formed in the rats exposed to hyperoxia was not significantly different between the Control (3.18 ± 0.16 ml) and Vitamin E (2.98 ± 0.38 ml), Spinach (3.40 ± 0.34 ml), or Blueberry (3.40 ± 0.22 ml).

Effects of diets and hyperoxia on lung antioxidant capacity. The effects of diets and hyperoxia on lung cytosol ORAC are shown in Table 3. Lung cytosolic ORAC\textsubscript{tot} decreased significantly with hyperoxia in all groups. Lung cytosolic ORAC\textsubscript{PCA} decreased significantly with hyperoxia in Control, Vitamin E, and Spinach groups (ANOVA, effect of oxygen, \(P < 0.05\)) but not in the Blueberry group.

**DISCUSSION**

The free radical theory of oxygen toxicity is generally accepted. According to this theory, oxygen toxicity is a result of the overproduction of ROS. The primary site of injury in normobaric oxygen toxicity is the lung. One of the characteristics of oxygen toxicity is the increased capillary permeability resulting in lung edema and pleural effusion. However, when the free radical theory was tested in vivo, nonenzymatic parameters were usually examined in lung and serum or plasma but not at the pleural effusion (1, 5, 25, 26, 35, 40). When such parameters were examined, only limited individual antioxidants were considered (1, 5, 25, 26, 35).

In the present study, the total antioxidant capacity in serum, lung, as well as pleural effusion was investigated by using the ORAC assay. Our results showed that hyperoxia caused 1) a decrease of protein concentration, an increase of ORAC\textsubscript{PCA}, and no change of ORAC\textsubscript{tot} in serum; 2) a decrease of both ORAC\textsubscript{PCA} and ORAC\textsubscript{tot} in lung; and 3) the formation of pleural effusion, which had the same protein concentration and ORAC\textsubscript{PCA} as serum did. Although the parameters measured in this study were obtained under static conditions, we have developed a dynamic model to help understand some of the changes observed. These results can be explained by using the model depicted in Fig. 2. The opposing movements of albumin, a macromolecular antioxidant, and LMW antioxidants between the bloodstream and lungs during hyperoxia result in the unchanged ORAC\textsubscript{tot} in serum, which measures both albumin and LMW antioxidants. Under normal conditions, the LMW antioxidant concentration in lung cytosol is much higher than that in serum, as demonstrated in this study using the ORAC\textsubscript{PCA} assay, which measures the total antioxidant capacity from nonprotein components extracted with PCA. The ORAC\textsubscript{PCA} in lung cytosol (3.2 ± 0.2 mM Trolox equivalents, \(n = 22\)) was more than fivefold that in serum (0.6 ± 0.02 mM Trolox equivalents, \(n = 22\)) in the air-exposed rats. The movement of LMW antioxidants from the lung into the bloodstream during hyperoxia caused the increase of serum ORAC\textsubscript{PCA} and the decrease of lung ORAC\textsubscript{PCA}.

Increased consumption of fruits and vegetables has been associated with protection against various diseases (18, 34, 36). It is not known what active dietary constituents contribute to these protective effects, but it is often assumed that antioxidant nutrients contribute to this defense (3, 4, 21, 42). By using ORAC assay, we found that blueberries and spinach had high antioxidant capacities (9, 32), which were 20–50 times higher than that of some other fruits and vegetables, such as honeydew melon and cucumber, on a fresh-weight basis. The results of the present study suggested that the hyperoxia-induced redistribution of proteins and LMW antioxidants between bloodstream, lung, and pleural effusion was blocked, at least in part, by dietary supplementation of blueberry extract for 8 wk. The blueberry extract significantly increased se-
tein concentration was significantly higher and the absorbed in rats (30). Anthocyanins protected against the plant extracts used in this study were not extensively could be antioxidants or non-antioxidants. Although ORACtot (Table 2). Therefore, the blueberry composition of proteins and LMW antioxidants, although the spinach treatment also significantly increased serum components responsible for the effects of blueberry extract must be different from the components in spinach; an equal amount of antioxidant activity from components responsible for the effects of blueberry extract may be respon-
tive effects but may not be the only or primary reason. Therefore, anthocyanins or other, as-yet-unidentified, properties of anthocyanins may contribute to these protective effects but may not be the only or primary reason. Therefore, anthocyanins or other, as-yet-unidentified, components of the blueberry extract may be responsible for the observed protection against the hyperoxia-induced increase in capillary permeability.

In summary, hyperoxia caused significant changes in antioxidant capacity in rat serum and lung. These changes were modulated by the dietary supplementa-
tion of an aqueous extract from blueberries, but not by vitamin E or an aqueous extract from spinach.
