ABSTRACT

Neutrophils traversing the pulmonary microcirculation are subjected to mechanical stimulation during their deformation into narrow capillaries. To better understand the time-dependant changes caused by this mechanical stimulus, neutrophils were caused to flow into a microchannel, which allowed simultaneous visualization of cell morphology, and passive rheological measurement by tracking the Brownian motion of endogenous granules. Above a threshold stimulus, mechanical deformation resulted in neutrophil activation with pseudopod projection. The activation time was inversely correlated to the rate of mechanical deformation experienced by the neutrophils. A reduction in shear moduli was observed within seconds after the onset of the mechanical stimulus, suggesting a sudden disruption of the neutrophil cytoskeleton when subjected to mechanical deformation. However, the magnitude of the reduction in moduli was independent of the degree of deformation. Recovery to nearly the initial values of viscoelastic moduli occurred within one minute. These observations confirm that mechanical deformation of neutrophils, similar to conditions encountered in the pulmonary capillaries is not a passive event, rather, it is capable of activating the neutrophils and enhancing their migratory tendencies.

KEYWORDS: viscoelasticity, cell activation, multiple-particle-tracking, PDMS
INTRODUCTION

Neutrophils often encounter narrow capillary segments during their transit through the pulmonary and systemic microcirculations. Since neutrophil diameters (6-8 µm) often exceed the diameter of a pulmonary capillary (2-15 µm) (5), neutrophils would almost certainly have to deform in passing from arteriole to venule, particularly in the pulmonary capillary bed, where it has been estimated that a typical flow pathway encompasses 50 to 100 such capillary segments (13; 14). Measurements of neutrophil shape showed that neutrophils in capillaries are elongated while those in arterioles are nearly spherical, thus confirming the view that neutrophils deform when they encounter narrow capillary segments (5; 12).

Mechanical forces have been recognized to play an important role in modulating the behavior and function of cardiovascular cells in health and disease (15; 17). Although the effects of mechanical stimuli on cells have been a topic of extensive research, much of the focus has been on endothelial cells in the context of atherosclerotic disease. Neutrophil, and leukocyte activity in general, is assumed to be mediated in large part by biochemical factors, with effects from mechanical stimulation often ignored. However, recent studies have shown that leukocytes are sensitive to fluid shear stress, which can influence their degree of substrate adhesion and the formation of pseudopods, and reduce their cytoskeletal stiffness (2; 22; 28). Similarly, the mechanical deformation of neutrophils into narrow pulmonary capillaries, initially considered to be a passive process, is now recognized to enhance adhesiveness to ICAM-1 through upregulation of CD11b/CD18, reorganizing and stabilizing the cytoskeleton and increasing free [Ca²⁺], (21). Consequently, neutrophils likely have the capability of sensing mechanical force or deformation and altering their rheological properties in response. Despite the importance of these effects in the microcirculation, no rheological studies have yet been conducted subjecting neutrophils to the deformations they experience while traversing the pulmonary circulation. Interestingly, one of the established techniques for measuring the viscoelastic properties of neutrophils, the
micropipette aspiration method, involves deformation of the cell under a fixed suction pressure into a narrow micropipette (9; 29; 32; 33). This technique mimics the flow condition that the cell experiences while deforming into a pulmonary capillary. The rheological properties deduced from this technique, however, assume that the neutrophil remains passive during deformation, and hence, that its rheology is unchanged when drawn into the pipette. Indeed, some of these micropipette experiments showed some indications of neutrophil activation attributed to mechanical deformation of the cell (8).

In such cases for which mechanical deformation by external forces give rise to a change in rheological properties, it is advantageous to seek methods of measurement that avoid cell manipulation. Multiple-particle-tracking microrheology (23; 24; 34) offers a solution as this method is able to non-invasively measure the local viscoelasticity by monitoring the Brownian motion of endogeneous granules present in the cytoplasm of the cell. A similar technique has been applied to locomoting neutrophils, with active manipulation of a granule using an optical trap (37; 38). In order to examine the effects of mechanical deformation on the behavior and rheological properties of the neutrophils in the pulmonary capillaries, we used microfabrication techniques (27; 35) to construct an in-vitro poly-dimethyl-siloxane (PDMS) system with dimensions comparable to the pulmonary capillaries. PDMS being optically transparent enabled direct observation of the neutrophil morphology, and simultaneously allowed us to employ the technique of multiple-particle-tracking microrheology to directly measure the viscoelastic properties of the cell.

MATERIALS & METHODS

Design and Fabrication of Microfluidic Device

The design of the microchannel used to mimic a pulmonary capillary and the connecting reservoirs is shown in Fig. 1. A master for this design was fabricated on silicon wafer using the technique of two-level photolithography (20), and subsequently used for replica molding in
PDMS (18). Fig. 2 shows the finished microfluidic system. The details of the fabrication process can be found in Appendix 1.

**Macrofluidic System Setup**

Pressure differential was imposed across the microchannel by varying the difference in height of water between the upstream and downstream macro-reservoirs (Fig.3). Two upstream macro-reservoirs were used: a high pressure (~ 60 cm H$_2$O) reservoir for purging and cleaning, and a low pressure reservoir for neutrophil perfusions. The upstream low-pressure macro-reservoir was attached to a linear translation stage (Edmund Optics, Barrington, NJ), and mounted on a linear slide (Rapid Advance Unislides, Velmex, Inc., Bloomfield, N.Y.) enabling both fine-scale (0.01 mm steps) and coarse-scale (1 mm steps) adjustment. A syringe attached to the second port of the upstream microfluidic reservoir allowed the introduction of fluid or cells into the device.

**Neutrophil Isolation**

Human venous blood was drawn from healthy volunteers by venipuncture into syringes containing 0.1 M sodium citrate as an anticoagulant. The isolation was in accordance with a protocol approved by the M.I.T. Committee on Use of Humans as Experimental Subjects. Neutrophils were isolated from mononuclear cells by density gradient centrifugation on Histopaque –1077 (Sigma-Aldrich, St. Louis, MO) at 175 g for 30 min at room temperature. The supernatant plasma layer was collected for later use in the experiment. The mononuclear layer was carefully removed, and the remaining neutrophil and red blood cell (RBC) layers were resuspended in first, an equal volume of HBSS without Ca$^{2+}$ or Mg$^{2+}$ (Invitrogen Corp., Carlsbad, CA), and then a 1:1 dilution of dextran (average molecular weight 500,000, 2% final concentration, Pharmacia Corp., Peapack, NJ). The RBCs were allowed to sediment for 30 min at room temperature, after which, the neutrophil-rich supernatant was collected, rinsed with
HBSS, and centrifuged at 175 g for 5 min at room temperature. Residual RBCs were removed by hypotonic lysis. Isotonicity was restored by the addition of 45 mls of HBSS without Ca\textsuperscript{2+} or Mg\textsuperscript{2+} and the sample was then centrifuged at 175 g for 5 min at room temperature. The isolated neutrophils were resuspended in either HBSS without Ca\textsuperscript{2+} or Mg\textsuperscript{2+} only, or in medium (HBSS without Ca\textsuperscript{2+} or Mg\textsuperscript{2+} + 2% autologous plasma). After counting, the neutrophil concentration was adjusted to 1.0×10\textsuperscript{6} cells/ml, and depending on experimental requirements, the cells were kept either at room temperature or incubated in a 37°C water bath.

**Optical Microscopy**

Neutrophils were observed using a differential interference contrast (DIC) microscope (Eclipse TE2000, Nikon Inc., Melville, NY) equipped with an oil immersion condenser lens (N.A. 1.4) and a 100×/1.4N.A. Plan Apochromat objective lens. Images were acquired with a video camera (CCD-100, Dage-MTI Inc., Michigan City, IN), and recorded onto a SVHS tape at 30 frames/s with a cassette recorder (SVO-9500MD, Sony Corporation, New York, NY). The movies were then converted into digital form with a computer equipped with a frame grabber card (Scion LG-3, Frederick, MD).

**Deformation and Trapping of Neutrophils inside Microchannel**

The microfluidic device was first incubated with 1% Pluronic F108 solution (PEO/PPO/PEO triblock copolymers, BASF Corp, Mount Olive, NJ) in water for 2 hrs, which served to passivate the PDMS surface and deter cell adhesion (19). The device was then flushed with medium (HBSS without Ca\textsuperscript{2+} or Mg\textsuperscript{2+} + 2% autologous plasma) for 15 min. An objective heater (Bioptech Inc., Butler, PA) set to 37°C, was used for experiments at body temperature.

Neutrophils suspended in medium were then introduced into the upstream microfluidic reservoir. By setting the upstream two-way valve to open to the upstream high pressure macro-reservoir, the cells flowed quickly towards the microchannel entrance zone. In addition, yellow-
green fluorescent 0.1 μm microspheres (carboxylate-modified polystyrene fluospheres, Molecular Probes, Eugene, OR), diluted in HBSS (w/o Ca²⁺ or Mg²⁺) at a concentration of 5×10⁸ beads/ml, were introduced into the upstream microfluidic reservoir and used to establish the zero pressure difference, zero flow condition.

Finally, the low-pressure macro-reservoir was raised to impose the desired pressure differential across the channel, initiating a flow of neutrophils into the microchannel. Once a neutrophil had entered the microchannel, the low-pressure macro-reservoir was returned to its initial height, immediately stopping its flow through the channel.

**Entrance Time and Time to Pseudopod Projection**

Neutrophil behavior was recorded from the start of its deformation into the channel up to the formation of the first pseudopod projection either at the leading or trailing edge of the cell. The playback of the video recording allowed precise determination of neutrophil entrance time and the first observation of pseudopod projection. The entrance time was taken to be the interval between when the neutrophil leading edge touched the channel entrance (first contact) and when the trailing edge cleared the channel mouth after deformation. The time to pseudopod formation was defined as the time from first contact to the first appearance of the pseudopod projection.

**Viscoelastic Properties of the Neutrophil Evaluated Using Multiple-Particle-Tracking Microrheology**

Brownian motion of endogeneous granules inside the neutrophils was monitored using particle-tracking algorithms (3) written in the IDL software (Research Systems, Boulder, CO) from the instant the neutrophil was trapped in the microchannel until the observation of pseudopod projection. The focal plane for particle tracking was selected near the center of the microchannel in order to minimize wall effects. From the video images, the cytoplasm of the neutrophil was divided into two zones (Fig. 4); zone 1, just proximal to the nucleus, and zone 2, the remainder of the cytoplasm up to the cell tip. Granules in zone 1, as well as granules
exhibiting obvious directed active movements in both zones were excluded from particle tracking. In addition, only granules that appeared circular were selected for tracking, achieved by setting the computer algorithms to track particles with eccentricity of 0.3 or less (major and minor axis difference of less than 5%). Only particles that remained in focus for at least 30 frames were analyzed. Because of the high density of granules present in the neutrophil cytoplasm, all the tracks performed by the computer algorithms were visually checked with the original video images to ensure that the same particle was followed throughout a particular track. From these particle trajectories, mean-square displacements (MSD) and the frequency-dependent elastic modulus, $G'(\omega)$, and loss modulus, $G''(\omega)$, were computed according to the methods of Mason et al. (26). The shortest time lag of 1/30s was chosen for these viscoelastic calculations as it gave the best statistical accuracy. The radius of a typical neutrophil granule was taken to be 300 nm (37) in these computations. Temporal changes in $G'$ and $G''$ were examined by performing independent analysis on 5 s time intervals.

As control, the multiple-particle tracking technique was also performed on round passive neutrophils (Fig. 5A). Neutrophils suspended in medium were introduced into a small chamber formed between a glass slide and coverslip. Again, granules close to the nucleus were excluded from the particle track.

Studies were also performed on adherent and spread neutrophils (Fig. 5B) on a glass coverslip. Neutrophils suspended in HBSS without Ca$^{2+}$ or Mg$^{2+}$, were introduced into a glass slide and coverslip chamber as before. The absence of plasma in the suspension resulted in adhesion and spreading. Only granules in the cytoplasm which were located at least 2 $\mu$m away from the nucleus of the cell were tracked. Values obtained for $G'$ and viscosity, $\eta$, at 1 Hz were compared with published results of non-invasive intracellular measurement of neutrophils (37). Because the measurements were performed at a higher frequency to allow comparison with the published data, particles chosen for tracking were in focus for at least 100 frames.
Statistical Analysis

All results are expressed as the means ± SE. Comparisons of data were carried out using the paired, two-tailed student t-test, and findings that showed either p<.05 or p<.01 were considered significant.

RESULTS

Neutrophils were introduced into microchannels comprising two different cross-sectional dimensions; a larger cross-sectional area with dimensions of 5 µm in width (W) and 2.5 µm in height (H), and a second smaller area with channel width of 5 µm and height of 1.5 µm. The effective diameter, $D_{eff}$, of the microchannels was calculated using the relationship

$$D_{eff} = \sqrt{\frac{4WH}{\pi}}$$

hence, giving us effective diameters of 4.0 µm and 3.1 µm, denoted by $D_L$ and $D_S$, respectively. Most experiments were carried out at 37°C, but some were also conducted at 23°C in order to examine the temperature-dependent behavior of the cell. We found experimentally that the threshold pressure for the cell to successfully deform into the microchannels was ~ 0.4 mm H$_2$O for $D_L$, and ~ 2 mm H$_2$O for $D_S$. Therefore, different pressure ranges were used for the two channels: $\Delta P = 1, 10$ and 50 mm H$_2$O for $D_L$, and $\Delta P = 10$ and 50 mm H$_2$O for $D_S$. These values of $\Delta P$ chosen were above the threshold pressure for the respective channel diameters, but within physiological limits experienced by neutrophils in pulmonary capillaries (16).

Typical trajectories of the granules, individual MSD and average MSD plots for neutrophils before and after mechanical deformation are shown in Figs 5C-E. A representative sequence of events during neutrophil deformation, followed by trapping and, ultimately, pseudopod formation is depicted in Fig. 6. The location of pseudopod projection occurred randomly (either at the leading or trailing edge of the cell but never at both sites). Following
pseudopod formation, the cell would begin to crawl along the microchannel in the direction of the pseudopod protrusion.

An increase in $\Delta P$ resulted in a decrease in entrance time (Fig. 7) as evidenced for example by comparing the data for $D_L$, 1 mm H$_2$O, 37°C and $D_L$, 10 mm H$_2$O, 37°C. Increasing the cross sectional area of the microchannel produced a similar effect ($D_s$, 10 mm H$_2$O, 37°C vs. $D_L$, 10 mm H$_2$O, 37°C), as was the case when the temperature was raised from 23°C to 37°C (e.g. $D_L$, 1 mm H$_2$O, 23°C vs. $D_L$, 1 mm H$_2$O, 37°C).

The time to pseudopod formation is shown in Fig. 8 for different experimental conditions. Pseudopods were observed for $D_L$, 1 mm H$_2$O and $D_L$, 10 mm H$_2$O at 37°C, but not for similar conditions at 23°C. Only when $\Delta P$ was raised to 50 mm H$_2$O for the case of $D_L$, 23°C, was pseudopod projection observed, and then, only after ~100s from the time of cell entry into the channel. For $D_L$, 1 mm H$_2$O, 23°C and $D_L$, 10 mm H$_2$O, 23°C, no pseudopod projection was observed even though the cells were monitored for >10 min.

Since the time to pseudopod activation varied with temperature, we focused on the conditions at 37°C to examine the effect of entrance time. Comparison of experiments carried out at 37°C (Fig. 9) showed a clear inverse correlation between deformation rate (computed as the inverse of entrance time) and the time of pseudopod formation. These results suggest that neutrophil activation as reflected by pseudopod formation will occur more rapidly when neutrophils are subjected to a higher rate of deformation.

To investigate the effects of mechanical deformation on the viscoelastic properties of neutrophils, we used the multiple-particle-tracking method. The technique was first applied to adherent and spread neutrophils (Fig. 5B). Measurements at 1 Hz (see Table 1) revealed an elastic modulus, $G'$, of $43.8 \pm 5.0$ dyn/cm$^2$, and viscous modulus, $\eta$, of $2.2 \pm 0.3$ dyn-s/cm$^2$. Round, passive neutrophils introduced into the glass slide-coverslip chamber and allowed to settle on the coverslip were also studied. Due to the presence of plasma in their surrounding medium,
the majority of the neutrophils (~98%) remained round (Fig. 5A) and free of pseudopod projection. Some of these adhered non-specifically to the coverslip whereas the rest floated loosely at the bottom of the chamber. Because the round, adherent cells remained stationary, they were chosen for particle tracking. The viscoelastic values of neutrophils were $G' = 242 \pm 21$ dyn/cm$^2$ and $G'' = 470 \pm 40$ dyn-s/cm$^2$ at 37$^\circ$C, as summarized in Table 1. These values were significantly lower (p<0.05) than the viscoelastic moduli at 23$^\circ$C ($G' = 303 \pm 19$ dyn/cm$^2$ and $G'' = 649 \pm 55$ dyn-s/cm$^2$), highlighting the effect of temperature on the mechanical properties of the cell.

In order to study the effect of mechanical deformation on the viscoelastic properties of neutrophils, particle tracking was performed once the cells had entered the microchannel. The experiments were carried out at 37$^\circ$C. The motion of neutrophil granules was monitored as soon as the cell was immobilized and the image focused. Tracking continued until the first observation of pseudopod projection, beyond which the cell began to crawl and granular motion became erratic, complicating the analysis. The temporal changes in $G'$ and $G''$ for the different flow conditions are shown in Figs. 10 and 11, respectively. Using values obtained for passive, round neutrophils (Table 1) as controls, the data show that mechanical deformation causes a significant drop (p<0.05) in $G'$ and $G''$. For all the flow conditions, the mean value of $G'$ was reduced by approximately 50-60% from its pre-deformation value of 242 dyn/cm$^2$. Similarly the mean value of $G''$ was reduced by approximately 35-50% after deformation. Interestingly, although mechanical deformation resulted in a softer and less viscous cytoplasm, the drop in magnitude of $G'$ and $G''$ was quantitatively similar and was independent of the degree of deformation. For the flow conditions of [D$_l$, 1 mm H$_2$O, 37 deg], [D$_l$, 10 mm H$_2$O, 37 deg] and [D$_s$, 50 mm H$_2$O, 37 deg], the cell maintained the softer, lower viscosity properties until pseudopod projections appeared. However, for the flow condition of [D$_s$, 10 mm H$_2$O, 37 deg], after the initial drop, $G'$ and $G''$ was seen to recover to roughly its pre-deformation value before pseudopod projection. This flow condition corresponded to the case of lowest rate of deformation in Fig. 9.
Although quantitative particle-tracking was not possible once the neutrophils begin to crawl, observation of random granule motion of the neutrophils showed periodic cycling of enhanced and reduced motion paralleling the cyclic projection of pseudopods during cell locomotion. The granules at the pseudopod leading edge were seen to have increased activity when a new wave of granules first flowed into the pseudopod, however, the granule activity soon diminished and remained low even during the next cycle of pseudopod projection. Only after the new pseudopod had fully extended would granular motion increase again when the next wave of granules entered the newly formed pseudopod. These observations are consistent with those seen in neutrophils locomoting on a flat substrate (37).

**DISCUSSION**

This study provides direct evidence that mechanical force of a magnitude comparable to that encountered by a neutrophil during transit through the microcirculation exerts a strong and fundamental effect on cell structure and function. The consequences of mechanical stimulation are immediate, occurring within seconds of stimulation, and substantial. A drop in shear modulus by more than 60% is observed within seconds of entering a constriction, independent of magnitude of the stimulus. In contrast, pathways leading to migratory behavior are excited in a strain rate-dependent manner, suggesting that these two phenomena may be independently controlled. Taken together, these results suggest an important role for mechanical stimulation of neutrophils, influencing both their rheology and their migratory tendencies.

The combination of microfabrication and particle tracking microrheology allowed us to simultaneously visualize and quantify the response of neutrophils. Previous studies of neutrophil deformation have been conducted using in-vitro filtration (7; 21; 31) or micropipette aspiration (6; 30). In the former, large cell numbers enabled studies of changes in deformabilities and biochemical analysis of the changes in F-actin content and free [Ca$^{2+}$]i, for example, but direct rheological measurements were not possible. Micropipette experiments provide data on cell
rheology, determined from entrance times, but provide limited data on time-dependent changes in viscoelastic properties or changes in specific cell constituents. Analysis of the thermal motions of endogenous granules would be difficult in this situation due to the requirement of high resolution optics. In particular, methods used previously to infer rheological properties from micropipette aspiration times assume that the rheological parameters are constant in time and unaffected by the mechanical forces imposed during manipulation of the cell. Our results suggest that this may not be a valid assumption.

The microfluidic device was coupled to a macrofluidic system consisting of a set of reservoirs. Pressure difference was imposed across the microchannel by varying the height of water in the reservoirs. The threshold pressure, \( \Delta P_{\text{thr}} \), for \( D_L \) and \( D_S \) in the experiment was compared with the theoretical expression, \( \Delta P_{\text{thr}} = 4\gamma \left( \frac{1}{D_{\text{pipet}}} - \frac{1}{D_{\text{cell}}} \right) \), where the cell cortical tension, \( \gamma = 35\text{pN/\mu m} \) has been measured previously (39). Due to the rectangular cross-section used in the present experiments, we can make only an approximate comparison by substituting \( D_{\text{eff}} \) for \( D_{\text{pipet}} \). Doing so, we find that the experimentally measured values of \( \Delta P_{\text{thr}} \) (0.4 and 2.0 mm H\(_2\)O for the large and small channels, respectively) are somewhat lower than the theoretically predicted values of 1.9 and 2.7 mm H\(_2\)O but this difference could be attributable to the different cross-sectional shape or entrance geometry. In contrast, entrance times observed in the present experiments were approximately 40 times smaller than those reported in the literature for micropipette aspiration under similar driving pressures and diameters. Cross-sectional shape might also influence entrance times, but the entrance geometry also likely contributes. Previous numerical simulations have shown that entrance times depend strongly upon the axial radius of curvature of the entrance (1). This would be consistent with the observation that the entrance to our microchannels tends to be somewhat more rounded than that of a micropipette. However, aside from a slight lowering of the threshold pressure and shorter entrance times, the effects of
driving pressure, channel cross-sectional area and temperature (Fig. 7) are generally consistent with previously published results (8).

Mechanical deformation of neutrophils into the pulmonary capillaries induced pseudopod formation for all experimental conditions at 37°C but only at the higher values of ΔP for experiments at 23°C (Fig. 8). Comparing similar experimental conditions, it took considerably longer for pseudopod projection at the lower temperature (10-30 s at 37°C, and ~100s at 23°C). Furthermore, the results indicate that for a given temperature, the time to pseudopod projection is inversely correlated to the rate of deformation of the neutrophil (Fig. 9), which we use here as a measure of the stimulus magnitude. These results are consistent with observations of activation reported in a previous micropipette aspiration study (8) that reported a transition from passive to active motile state, with activation time varying between 0 and 120 s at 37°C and between 60-120 s at 23°C. Hence, our results confirm that mechanical deformation is not a passive event; that rather, it leads to neutrophil activation with pseudopod formation if the stimulus is sufficiently large. Above the threshold stimulus, it appears that the time required for activation is dependent upon the rate of deformation experienced by the cell, implying the existence of a mechanosensing or signal transduction mechanism in the cell that is able to modulate the response according to the magnitude of the mechanical stimulus. In contrast, we found that neutrophil entrance time behaved in a manner more consistent with a passive cell in that it was determined primarily by the initial value of the shear modulus, which was only slightly dependent upon temperature. (Fig. 7).

Our measurements of viscoelastic moduli of adherent, spread neutrophils obtained using the particle tracking system (Table 1) can be compared with published results of Yanai et al., who reported mean values of $G' \approx 10$ dyn/cm$^2$ and $\eta \approx 4.0$ dyn-s/cm$^2$ for the body and trailing region of the neutrophil using an optical trap to excite the granules at frequencies between 0.3 and 3 Hz. Our measurements for $\eta$ matched closely with the previously published results while the value
for $G'$ was about 4 times higher. One potential explanation for this difference is that the optical trap technique was capable of measuring only those granules that were freely moving, while other particles were too stiff to be oscillated at maximum laser power.

Table 1 also shows the ratio of $G''/G'$ for the measurements carried out on adherent, spread neutrophils and those for passive, round cells at 37°C and 23°C. Our value of $G''/G'$ of 0.32 for adherent, spread neutrophils matches the value of ~0.3 obtained at 0.75 Hz using magnetic twisting cytometry (10). However, there are no similar figures reported in the literature for passive, round cells. Nevertheless, the values of $G''/G'$ of ~2.0 for passive, round cells is within the limits of the values (0.25 to 20) reported for other cell types using various experimental techniques (10; 34; 36).

In order to gain further insight into the effects of mechanical deformation on the cytoskeletal structure of the neutrophil, the granules of the neutrophils were tracked to monitor the change in rheology of the cell before and after deformation. Mechanical deformation results in a reduction in elastic moduli by 50-60%, within 10-15 s after the initial stimulus, from its value as a passive, round cell before deformation (Figs. 10 and 11). Similarly, the loss moduli drop by 35-50% from the cells’ unactivated values. These data demonstrate that mechanical deformation causes either disruption or remodeling of the neutrophil cytoskeleton. In view of the decrease in viscoelastic properties of the cell, this might be due either to a sudden depolymerization of filamentous actin or rupture of cross-links bridging between actin filaments. The lack of a significant temperature effect on entrance time, in combination with the short time scale of the modulus changes (~10s), leads us to favor the theory that the rapid deformation ruptures actin cross-links. In contrast, Kitagawa and co-workers (21), observed an immediate but short-lived increase in F-actin, leading them to conclude that mechanical deformation resulted in increase in actin cross-linking events rather than actin polymerization. Further experiments are required to reconcile these seemingly contradictory results.
Another interesting observation is that the magnitude of drop in the values of $G'$ and $G''$ after deformation was found to be independent of the degree of deformation. This is in contrast with the time to pseudopod formation which correlates with the rate of deformation. Also, neutrophils subjected to low deformation rates were observed to recover much of their modulus reduction within ~30 s and return nearly to their initial mechanical state. These data suggest that the extent of depolymerization or loss of actin-cross linking is similar regardless of the magnitude or rate of deformation, at least within the range of these experiments, but the initiation of actin polymerization to form pseudopods is dependent on the magnitude of force transduced. One scenario consistent with these observations is that the large strain deformations effectively shear and rupture many of the actin cross-links, leaving them attached to one filament but displaced relative to their initial cross-linking site. Once the deformation stops, these cross-links can reform, but do so in the new, deformed state, returning the cell to its initial mechanical state but in a new, deformed geometry. Thus, it appears that the molecular mechanism controlling the depolymerization/actin crosslink breakdown is separate from the mechanism governing pseudopod formation and viscoelastic recovery, however further experiments would be needed to confirm this.

This evidence of viscoelastic recovery could help explain results from neutrophil recovery experiments after deformation into micropipettes (32). In that study, neutrophils were aspirated fully into a micropipette and held for a various periods of time before being expelled. Cells held in the micropipette for a short time ($< 5$s) exhibited a rapid elastic rebound immediately after being expelled from the pipette. In contrast, neutrophils held for longer times ($> 5$s) displayed a smoother recovery, and took much longer to recover to their spherical shape ($\sim 75$ s to reach 90% of its full recovery compared to $\sim 55$s for the short holding time). These observations can be explained on the basis of the rapid fall and slower recover of modulus following deformation observed in the present experiments. Cells ejected immediately after being aspirated, would have a low internal modulus and few cross-links, thus their surface tension
could rapidly return the cell to a spherical shape. Cells held for a longer period, would remodel due to reformation of actin cross-links; upon ejection the cell would need to remodel once again, but this time under the action of a much smaller restoring force, that due to surface tension alone.

We recognize that the multiple particle tracking technique used in this investigation has limitations especially when compared to the recently developed method of two-particle microrheology (4; 11). In multiple particle tracking, granule size must be estimated, introducing error (approximately a factor of 2) into the viscoelastic modulus obtained. In two-particle microrheology, the cross-correlated motion of pairs of particles is independent of particle size and shape and is unaffected by the coupling between the particles and the medium. Unfortunately, measurement by the two-particle technique requires data collection over a much longer period of time than the multiple particle tracking method, hence preventing us from monitoring temporal changes in the cell. The two particle microrheology technique is more suitable for measurements where the behavior of the cells is relatively unchanged over the period of data collection (25). Thus, we resort to the multiple particle tracking method in the present study, and in the application of this technique, we maximized the accuracy of the results by eliminating granules that are not circular and also selecting granules of almost equal size. Since active motion can only cause an apparent reduction in modulus (greater granular motion), however, these results represent a lower bound on modulus.

In summary, this study shows that mechanical deformation of neutrophils into pulmonary capillaries results in activation of the cell by inducing cytoskeletal remodeling, leading to changes in viscoelastic properties and pseudopod projection. Hence, mechanical deformations are capable of activating a neutrophil, providing a migratory stimulus and thereby enhancing their tendency to transmigrate across the endothelium.
ACKNOWLEDGEMENTS

The authors thank Thierry Savin and Patrick S. Doyle for assistance with particle tracking, Jorge M. Ferrer and Matthew J. Lang for microscopy assistance and Hayden Huang for cell preparation. Appendix 1

The design of the microchannel was drawn in AutoCAD (Autodesk Inc., San Rafael, CA) for fabrication on chromium masks (Photronics Inc., Brookfield, CT) (Fig. 1). The fabrication of the master utilized the technique of two-level photolithography. Silicon wafers (100mm, 425-525 μm, 1-10 Ω – cm, [1-0-0]; Transition Tech. Int., Sunnyvale, CA) were spin-coated with the first layer of SU-8 2002 photoresist (Microchem Corp., Newton, MA) to a thickness of either 1.5 or 2.5 μm, and prebaked at 95°C for 2 min. The resist was then exposed to UV light with an intensity of 10 mWcm⁻² for 11.5 s through the first chromium mask with features of the microchannel and the reservoirs. The resist was post-baked at 95°C for 2 min, which crosslinked the regions exposed to UV light. Next, a second layer of SU-8 2010 photoresist was spin-coated to a thickness of 15 μm on top of the first layer, followed by pre-baking at 95°C for 4 min. The second chromium mask with features of the reservoirs only was aligned, and the photoresist was exposed for 20 s. After post-baking again at 95°C for 3 min, SU-8 developer (Microchem Corp., Newton, MA) was used for 5 min to develop the features in both resist layers. Finally, the height of the microchannel was checked with a profilometer (Dektak 2, Veeco Instruments, Woodbury, NY).

When the master was successfully fabricated, the device was formed in PDMS by replica molding. The master of photoresist was first treated with trimethylchlorosilane (Sigma-Aldrich, St. Louis, MO) to prevent adhesion of PDMS to the master after curing. A curing agent and PDMS prepolymer (SYLGARD 184 Silicone Elastomer Kit, Dow Corning, Midland, MI) were mixed together and degassed for 5 min to remove air bubbles. The mixture was then poured onto the master and cured in an oven at 80°C for 3 hr. When cured, the PDMS was removed by peeling off the master. Inlet and outlet reservoir ports were formed by punching the PDMS with a 16-gauge adapter needle. Through these bored tunnels, inlet and outlet tubes would later be
inserted, which allowed connection of the microfluidic device to the external macrofluidic system described below.

The final step involved sealing the PDMS to a glass coverslip. The coverslip was also spin-coated with a thin layer of the same PDMS elastomer and cured in the oven. Both the microdevice and the coverslip were subjected to plasma oxidation for 30 s (Plasma Cleaner, Harrick Scientific Corporation, Ossining, NY), after which the surfaces were brought together to form an irreversible seal and produce the finished device (Fig. 2).

FIGURE LEGENDS

FIGURE 1. Schematic showing design of the microchannel and its connecting reservoirs. The microchannel section is enlarged to highlight the channel geometry. The important channel dimensions are: length 250 \( \mu \)m, width 5 \( \mu \)m and inlet radius of curvature 2.5 \( \mu \)m. Diagrams are not drawn to scale.

FIGURE 2. (Top) Schematic diagram of the finished PDMS microfluidic device with two inlet and one outlet reservoir ports. The device is sealed on a glass coverslip. \( H \) represents the microchannel height, which is either 1.5 or 2.5 \( \mu \)m. Diagram is not drawn to scale. (Bottom) Image of microchannel molded from PDMS as seen under a light microscope. Scale bar, 100 \( \mu \)m.

FIGURE 3. Schematic showing the macrofluidic system setup and its connections to the microfluidic device. Refer to Materials and Methods for explanation on the function of each of the system components.

FIGURE 4. Schematic diagram illustrating the division of the neutrophil cytoplasm into two regions; zone 1, proximal to the nucleus and zone 2, distal from nucleus up to the cell leading or trailing edge. Only granules dispersed in zone 2 were selected for particle tracking. \( L_i = \) length from nuclear boundary to the leading edge; \( L_t = \) length from nuclear boundary to the trailing edge.

FIGURE 5. (A) Image of a round, passive neutrophil. Clearly seen are the endogeneous granules in the cytoplasm of the cell. Scale bar, 5 \( \mu \)m. (B) Image of a neutrophil that had spread out on a coverslip showing many endogeneous granules dispersed throughout the cytoplasm. As described in Materials and Methods, only granules located at least 2 \( \mu \)m away from the nucleus.
(an example is shown with an arrow) were tracked while granules situated proximal to the nucleus were ignored in the tracking. Scale bar, 5 µm. (C) Individual MSD traces of randomly selected endogeneous granules for passive, round neutrophils (Inset) Typical trajectory of the centroid of a granule used to calculate the MSD. (D) Individual MSD traces of randomly selected endogeneous granules for neutrophils that have undergone deformation into a microchannel (Inset) Typical trajectory of the centroid of a granule used to calculate the MSD. (E) Typical plot of average mean-squared-displacement (MSD) curves for neutrophils before and after exposure to mechanical stimulation.

FIGURE 6. Image sequence showing a neutrophil flowing towards the microchannel entrance [panel (a)], the leading edge of the cell just crossing the channel inlet [panel (b)], the cell undergoing deformation [panel (c)], the trailing edge of fully deformed cell just clearing the channel mouth [panel (d)] and subsequently, the neutrophil was trapped in the channel [panel (e)]. After some time, the cell can be seen to form pseudopod projection [panels (f) to (h)]. Arrow in panel (f) points to the location at the trailing edge of the cell where pseudopod protrusion was first seen. Here, the neutrophil was flowing into D_L under pressure difference of 50 mm H_2O at 37°C. Scale bar, 5 µm.

FIGURE 7. Entrance time for different experimental conditions. Data are expressed as means ± SE. The number of observations, n, for the corresponding experimental conditions are as follows: D_L, 1 mm H_2O, 37deg (n=8); D_L, 10 mm H_2O, 37deg (n=8); D_S, 10 mm H_2O, 37deg (n=4); D_S, 50 mm H_2O, 37deg (n=4); D_L, 1 mm H_2O, 23deg (n=5); D_L, 10 mm H_2O, 23deg (n=8); D_L, 50 mm H_2O, 23deg (n=6)
FIGURE 8. Time to pseudopod projection for different experimental conditions. Data are expressed as means ± SE. The number of observations, n, for the corresponding experimental conditions are as follows: D_l, 1 mm H2O, 37deg (n=5); D_l, 10 mm H2O, 37deg (n=8); D_s, 10 mm H2O, 37deg (n=4); D_s, 50 mm H2O, 37deg (n=4); D_l, 50 mm H2O, 23deg (n=5). Not shown in the figure are data for D_l, 1 mm H2O, 23 deg (n=5) and D_l, 10 mm H2O, 23 deg (n=6), in which, no pseudopod projection was observed even though the cells were monitored for at least 10 min.

FIGURE 9. Effect of rate of deformation on time to pseudopod projection for neutrophils at 37°C.

FIGURE 10. Temporal change in elastic modulus, G’, of neutrophil after mechanical deformation into a microchannel, at a lag time of 0.03s. Graphs show changes in G’ under different flow conditions at 37°C. Time = 0 s represents the instance when leading edge of cell had just crossed the channel inlet. The time at which G’ could first be recorded varied due to dissimilar entrance time for the different flow conditions. Value of G’ for passive, round neutrophils at 37°C (Table 1) serves as control. Data are expressed as means ± SE. n = number of cells; N = number of granules; *P<0.05 and **P<0.01 when compared to control; †P<0.05 and ††P<0.01 when compared to data at t = 15s.

FIGURE 11. Temporal change in loss modulus, G”, of neutrophil after mechanical deformation into a microchannel, at a lag time of 0.03s. Graphs show changes in G” under different flow conditions at 37°C. Time = 0 s represents the instance when leading edge of cell had just crossed the channel inlet. The time at which G” could be first recorded varied due to dissimilar entrance time for the different flow conditions. Value of G” for passive, round neutrophils at 37°C (Table 1) serves as control. Data are expressed as means ± SE. n = number
of cells; N = number of granules; *P<0.05 and **P<0.01 when compared to control; †P<0.05 and ††P<0.01 when compared to data at t = 15s.
TABLE 1. Elastic modulus (G’), loss modulus (G”) and the ratio (G”/G’), each evaluated at a lag time of 0.03s, of adherent, spread neutrophils at 37°C and passive, round neutrophils at 37°C and 23°C. n = number of cells; N = number of granules.
