Abstract

Intravascular hemolysis is one of the most emphasized mechanisms for destruction of erythrocytes during and after physical activity. Exercise-induced oxidative stress has been proposed among the different factors for explaining exercise induced-hemolysis. The validity of oxidative stress following exhaustive cycling exercise on erythrocyte damage was investigated in sedentary and trained subjects before and after antioxidant vitamin treatment (A, C, and E) for two months. Exercise induced a significant increase in thiobarbituric acid reactive substance (TBARS) and protein carbonyl content levels in sedentary subjects and resulted in an increase of osmotic fragility and decrease in deformability of erythrocytes, accompanied by signs for intravascular hemolysis (increase in plasma hemoglobin concentration and decrease in haptoglobin levels). Administration of antioxidant vitamins for two months prevented exercise-induced oxidative stress (TBARS, protein carbonyl content) and deleterious effects of exhaustive exercise on erythrocytes in sedentary subjects. Trained subjects’ erythrocyte responses to exercise were different from sedentary subjects’ before antioxidant vitamin treatment. Osmotic fragility and deformability of erythrocytes, plasma hemoglobin concentration and haptoglobin levels were not changed after exercise although the increased oxidative stress was observed in trained subjects. After antioxidant vitamin treatment, functional and structural parameters of erythrocytes were not altered in the trained group, but exercise-induced oxidative stress was prevented. Increased percentage of young erythrocyte populations were determined in trained subjects by density separation of erythrocytes. These findings suggest that the exercise-induced oxidative stress may contribute to exercise-induced hemolysis in sedentary human.

Key words: hemolysis, sports anemia, osmotic fragility, deformability.
Introduction

Many hypotheses have been proposed to explain exercise-induced hemolysis (34, 37). Mechanical trauma by footstrike is accepted as a foremost factor that may contribute to exercise-induced hemolysis (38). However non-traumatic activities such as swimming, cycling, rowing and weight lifting have also given rise to significant erythrocyte destruction (37). Elevated body temperature, acidosis, elevated catecholamines, dehydration, hemoconcentration, and compression of erythrocytes in capillaries within the contracting muscles are some important mechanisms that play a role in non-footstrike intravascular hemolysis during regular or single bouts of exercise and/or recovery periods (34, 37). In addition to these mechanisms, exercise-induced oxidative stress can induce hemolysis as others and we reported (32, 33).

Free radicals are known to play a pivotal role in tissue damage, as well as having an adverse effect on erythrocytes (2, 36). It is well-known that there is a close relationship between oxidative stress and exercise. In addition to the emergence of free radicals from mitochondrial leakage owing to enhanced oxygen consumption, ischemia-reperfusion process and leukocyte activation may also contribute to oxidative stress during exercise (19, 20), especially in extramuscular tissues (heart, liver, brain) and erythrocytes. It is well documented that exercise-induced oxidative stress occurring in various tissues and blood can be prevented by antioxidant interventions in animals and humans (19, 31). Furthermore antioxidant vitamin supplementation also prevents certain hemolytic situations due to non-exertional oxidative stress (14, 18, 29, 40).

We previously demonstrated that a single exhaustive exercise period in sedentary rats promoted oxidative stress and lead to structural and functional deterioration in erythrocytes (32). One month antioxidant vitamin treatment prevented exercise-induced oxidative stress and also erythrocyte deterioration in sedentary rats after exhaustive exercise. However, this impact was not demonstrated in exercise-trained rats. The significant differences between red blood cells in rat and human prevent extrapolation of findings from one specied to the other. There are several structural differences between rat and human erythrocytes including cell size, membrane lipid and protein compositions, and membrane surface charge (4, 17). These structural differences between human and rat erythrocytes may lead to altered deformability, aggregation properties and also hemolysis (3, 4, 28, 30).
The aim of the present study was to determine the contribution of oxidative stress to exercise-induced hemolysis in sedentary and trained men before and after antioxidant treatment with A, C and E vitamins.

Materials and Methods

Subjects, Protocols, and Sampling

Twenty young male students from the Medical School and School of Physical Education and Sports of Akdeniz University volunteered for the study. Subjects were non-smokers and had no apparent health problems. The subjects were informed about procedures involved and any discomfort associated with the experiment before giving their written consents. The study was approved by the Ethical Committee of Akdeniz University and Ministry of Health. One student of School of Physical Education and Sports was withdrawn from the experiment by his own desire and one student from Medical School broke his arm during the experimental period. Nine students from Medical Faculty were included in the Sedentary Group. Students in this group were not engaged in any regular exercise activity, either personally or as group activity. Nine students from School of Physical Education and Sports who were on the university handball team were included in the Trained Group.

Maximal aerobic capacity (VO\textsubscript{2max}) of these subjects was assessed by a computerized, breath-by-breath analyzing system (Vmax Spectra 29 LV, Sensormedics, Ca, USA). The subjects performed the Bruce protocol on a motorized treadmill ergometer. Maximal aerobic capacity corresponded to the plateau in oxygen consumption, despite the increment in the work load. The physical, hematological and training characteristics of subjects are presented in Table 1.

All subjects participated twice in a cycling exercise test. After a two-minute warm-up, the workload test was started at 50 W and increased by 50 W every two minutes, while the subjects maintained a pedal frequency of 50 rpm. The tests lasted for 8-12 minutes, the time at which the subjects expressed their exhaustion or when maximal heart rate was attained, calculated as 220-age. At the end of the workload test, all subjects had a two-minute cool-down. All experiments were conducted in an exercise laboratory where room temperature varied between 20-23°C and humidity was 40 ± 10%. The first exercise test was performed before antioxidant vitamin treatment. Regular daily vitamin intake started one week after the first exercise test and continued for two months. All subjects utilized commercially available pills of vitamin A (\(\beta\)-carotene, 50 mg.day\(^{-1}\)), vitamin C (ascorbic acid, 1000 mg.day\(^{-1}\)) and vitamin E (\(\alpha\)-tocopherol, 800 mg.day\(^{-1}\)). The exercise test was repeated after the treatment
period in both groups. Both tests were applied to the trained subjects 48-72 hours after their last training session. Regular physical training continued during antioxidant treatment.

Venous blood samples were obtained from an antecubital vein before and after the aerobic exercise test and anticoagulated with sodium heparin (15 IU/ml). The first sample (basal) was obtained 10 minutes prior to the start of the exercise protocol. The remaining blood samples were obtained at 2, 12, and 24 hours after the exercise bout. These samples were used for the measurement of erythrocyte mechanics and hemolysis parameters, lipid peroxidation, protein oxidation, antioxidant defense system and density separation of erythrocytes. Blood lactate concentrations were also measured 5-min after termination of exercise by a lactate analyzer using BM-Lactate test strips (Accusport, Boehringer Mannheim, Germany).

**Erythrocyte Fragility and Mechanical Parameters**

*Osmotic Fragility.* Erythrocyte fragility was determined osmotically by the method of Beutler (8). Briefly, heparinesed whole blood (10 µL) was added to tubes with increasing concentration of buffered salt solution (pH 7.4, 0 - 0.3 - 0.35 - 0.4 - 0.45 - 0.5 - 0.55 – 0.6 – 0.7 – 0.9 %). The tubes were gently mixed and incubated at room temperature for 30 min. Then, the samples were centrifuged at 2000 rpm for 10 min and supernatants were collected. Optical density of the supernatant was measured by a spectrophotometer at 540 nm. Hemolysis in each tube was expressed as percentage, taking as 100% the maximum value of absorbance of the distilled water (0% concentration). The half maximal (50%) concentration values were calculated from the percentage hemolysis ($H_{50}$) in buffered salt solutions at various concentrations by GraphPad Prism 3.0 software program.

*Erythrocyte Deformability.* Red blood cell deformability was measured at various fluid shear stresses by laser diffraction analysis using an ektacytometer (LORCA, RR Mechatronics, Hoorn, The Netherlands). The principle of the system was described elsewhere in detail (16). Briefly, a low hematocrit red blood cell suspension in an isotonic solution of polyvinylpyralidon (6% in PBS, viscosity: 25.3 centipoise) is sheared in a Couette system composed of a glass cup and a precisely fitting bob, with a gap of 0.3 mm between the cylinders. A laser beam is directed through the sheared sample and the diffraction pattern produced by the deformed cells is analyzed by a microcomputer. Based upon the geometry of the elliptical diffraction pattern, an elongation index (EI) is calculated as: $EI = (L-W)/(L+W)$, where $L$ and $W$ are the length and width of the diffraction pattern. EI values were determined for nine shear stresses between 0.5 – 50 Pa. The shear stress required for half-maximal
deformation (SS_{1/2}) was calculated from the data set for each measurement by using a Lineweaver-Burk analysis procedure (5). Increased SS_{1/2} values represent the decreased deformability of erythrocytes. Briefly, the shear stress-EI curve was linearized by plotting the reciprocal of EI versus the reciprocal of shear stress, with the x-intercept of this line corresponding to the negative reciprocal value of shear stress causing half-maximal deformation (SS_{1/2}). All measurements were performed at 37 °C.

Plasma Hemoglobin Concentration. A modified method, based on cyanmethemoglobin was used for determining plasma hemoglobin concentrations and the values are expressed as g/dL (6).

Plasma Haptoglobin Concentration. A commercial nephelometric kit (Dade Behring, Marburg, Germany) was used for analyzing plasma haptoglobin concentrations.

Oxidative and Antioxidant Status Parameters

Thiobarbituric acid reactive substance. Lipid peroxidation of erythrocytes was estimated by the measurement of thiobarbituric acid reactive substance (TBARS) as described by Stocks and Dormandy (35) using 1,1,3,3-tetraethoxypropane as a standard. TBARS levels were determined by measuring absorbance at 532 nm after reaction with thiobarbituric acid in erythrocyte extracts.

Carbonyl derivative. Reactive carbonyl derivative content as a marker of protein oxidation was measured using method of Levine et al. (21). Since in our pilot study we observed that reactive carbonyl derivative content reached peak values earlier than TBARS, we decided to use 12 hour time point for protein oxidation analysis.

Antioxidant status. The activities of three antioxidant enzymes in erythrocytes and plasma levels of antioxidant vitamins were evaluated before and after antioxidant vitamin treatment. Catalase (CAT; EC 1.11.1.6), superoxide dismutase (SOD; EC 1.15.1.1) and glutathione peroxidase (GPX; EC 1.11.1.9) activities were assessed using the methods of Aebi (1), Misra and Fridovich (25), Paglia and Valentine (27) respectively. Vitamin A and C levels were analyzed using the methods of Mc Cormic (23). Levels of vitamin E were determined as described by Desai (13).

Density separation of erythrocytes

Density separation was applied to determine the ratio of erythrocyte age. Erythrocytes were separated according to their density using discontinuous Iodixanol (Optiperp, Nycomed Pharma As, Norway) density gradients (41). Iodixanol aliquots with densities between 1.075 -
1.085 – 1.095 – 1.105 - 1.115 g/ml (2 ml each) were layered on top of each other in a test tube. One milliliter of whole blood was carefully layered on top of the least dense layer and the tube was centrifuged at 2500 g for 25 min, at 22 °C. Each layer was carefully separated and the density distribution of erythrocytes was estimated by determining the hemoglobin concentration in each layer. Because erythrocytes density increases as a function of age (12), old cells accumulated at bottom (dense) layers of Iodixanol.

**Statistical Analysis**

The results were expressed as mean ± SE. Three-way ANOVA was used for statistical analyses. Training effect, antioxidant supplementation and acute exercise effect were chosen as independent parameters. Paired t-test was used for comparison of non-repeated parameters within the groups. Student’s t-test was used to compare non-repeated measurements between two groups (physical, hematological and training characteristics). P<0.05 was accepted as significant.

**Results**

All subjects completed both exercise protocols without problems before and after antioxidant treatment. Although maximal pulse rates and lactate concentrations were not different between groups, exercise durations of trained subjects were significantly greater than sedentary subjects before and after antioxidant treatment (p<0.01, p<0.05 respectively) (Table 2). None of these three parameters were altered by antioxidant treatment in both groups.

**Responses of Sedentary Subjects**

Osmotic fragility, deformability, plasma hemoglobin concentration and haptoglobin levels of sedentary group are shown in Figure 1. There were significant deteriorations in osmotic fragility and deformability in sedentary erythrocytes 24 hours post-exercise compared to basal levels prior to antioxidant treatment (p<0.05). Meanwhile plasma hemoglobin concentrations increased and haptoglobin levels decreased 24 hours post-exercise compared to basal values (p<0.05), as is typical of intravascular hemolysis. Erythrocyte deformability 2 hours post-exercise was also significantly increased compared to basal levels (p<0.05). There were no significant differences in osmotic fragility, deformability, plasma hemoglobin concentration and haptoglobin levels of sedentary group after antioxidant treatment.
TBARS and carbonyl derivative levels of sedentary groups are presented in Figure 2. Values of TBARS 24 hours post-exercise and protein carbonyl content 12 hours post-exercise were significantly increased, before antioxidant treatment compared to their basal levels (p<0.01). TBARS levels 2 hours post-exercise were also significantly higher than basal values (p<0.01). Two months of antioxidant vitamin therapy completely prevented the post-exercise increase in TBARS and carbonyl derivative levels.

Responses of Trained Subjects

Osmotic fragility, deformability, plasma hemoglobin concentration and haptoglobin levels of trained group are shown in Figure 3. There were no significant differences after the first exercise test in osmotic fragility, deformability, plasma hemoglobin concentration and haptoglobin levels of trained group compared to their basal values before antioxidant treatment except deformability of erythrocytes 2 hours post-exercise was significantly increased after antioxidant treatment (p<0.01).

Oxidative stress parameters of trained subjects were almost identical to those of sedentary ones (Figure 4). Before antioxidant treatment, protein carbonyl content 12 hours and TBARS levels 24 hours after exercise were significantly higher than their basal levels (p<0.05). Antioxidant treatment also attenuated the increase in TBARS and carbonyl derivative in trained subjects.

Although we observed significant time-dependent alterations within group analyses, oxidative stress parameters, erythrocyte fragility and mechanical parameters were not statistically different between the sedentary and trained groups according to multiple-way variance analysis results. However, variance analysis showed significant interactions between time-related alterations and antioxidant supplementation for oxidative parameters (TBARS, protein carbonyl content), suggesting that antioxidant treatment with vitamins A, C and E suppresses oxidative stress in both groups.

Density separation of erythrocytes

The density distributions of erythrocytes in sedentary and trained groups are shown in Figure 5. Erythrocytes in both groups were mostly accumulated in the layers with densities between 1.095-1.105 g/ml. In density layer 1.095, where younger erythrocytes accumulate, sedentary and trained erythrocytes’ percentages were 30.3±3.2 and 42.6±5.6, respectively (p<0.05). However, in density layer 1.105, sedentary and trained erythrocytes percentages were 48.6±1.7 and 42.4±3.7, respectively (p<0.01). In the first three layers, where younger
erythrocytes were concentrated, the percentage of erythrocytes from the sedentary group was 32.5 while in trained group it was 45.5.

**Antioxidant Status**

SOD, CAT, GPx activities in erythrocytes and antioxidant vitamin levels in plasma are presented in Figures 6 and 7. There were no differences in SOD values between both groups and within the groups before or after antioxidant treatment. CAT levels were significantly higher in trained subjects compared to sedentary subjects before antioxidant treatment, but not after treatment, while GPx levels were significantly increased in both sedentary and trained groups after antioxidant treatment (p<0.05, p<0.01 respectively). There were no significant differences in GPx levels between two groups. The measured antioxidant vitamin levels of sedentary and trained subject were similar before antioxidant treatment. Plasma vitamin A, C and E levels significantly increased in both groups after antioxidant treatment compared to their basal values.

**Discussion**

The results of this study demonstrated that a single bout of rigorous exercise was sufficient to elevate oxidative stress markers and induce deterioration of erythrocyte structure and function in sedentary young men, which but was preventable by two months of antioxidant vitamins treatment. However, this impact has not been demonstrated in trained subjects. This study also showed that the difference between sedentary and trained erythrocytes may partly be dependent on the younger erythrocyte population present in trained subjects. It is well known that regular physical activity triggers some accommodative processes thus the results of our study will be discussed separately on the basis of responses obtained from exercise trained and sedentary men.

**Responses of Sedentary Subjects**

Physical activity was demonstrated leads to lipid and protein oxidation via oxidative stress in many studies (20, 31). Sedentary subjects in our study also exhibited elevated levels of TBARS and carbonyl derivative, considered as markers for lipid and protein peroxidation, respectively. Although most studies indicate that exercise-induced oxidative stress predominates in the period just after the exercise, lipid peroxidation may increase later after exercise (20, 22, 24, 43). This delete increase in exercise-induced oxidative stress depends on
leukocyte and macrophage activation, and activation of xanthine oxidase due to ischemia-reperfusion process rather than the emergence of free radicals from mitochondrial leakage due to enhanced oxygen consumption during exercise (20, 39, 44). As we demonstrated in our previous pilot study that the time course of post-exercise induction of plasma protein carbonyl content is earlier than that observed with TBARS, we chose to present the protein carbonyl content results at 12 hours instead of 24 post-exercise in this study. Davies and Goldberg concluded that lipid peroxidation and protein oxidation involve different mechanisms in vivo and protein oxidation occurs more quickly than lipid peroxidation (10, 11).

Exercise induced oxidative stress occurring in various tissues and blood of experimental animals and human beings can be prevented by antioxidant interventions (19, 31). Taking advantage of these observations, we used a cocktail consisting of vitamins A, C and E to enhance antioxidant defense. Plasma A, C and E vitamin levels significantly increased after the two month treatment period. The basal levels of oxidative stress markers, determined after the two month treatment were slightly higher, though not significantly, in comparison with those before the vitamin treatment. However, no change in TBARS and protein carbonyl content was observed after the vitamin treatment in post-exercise period. It was observed that oral antioxidant treatment for two months significantly prevented exercise-induced oxidative stress.

Increased hemolysis caused by oxidative stress has been reported in several situations, such as sickle cell anemia, β-thalassemia, vitamin E depletion, hyperglycemia and exposure to H₂O₂, halothane and sulphur dioxide (7, 14, 15, 18, 40). In certain conditions, hemolysis of erythrocytes due to non-exertional oxidative stress was prevented with antioxidant vitamin supplementation, and hemolytic resistance of erythrocytes was enhanced (7, 14, 18, 29). In our previous study, the prevention of exercise-induced oxidative stress by antioxidant vitamins was associated with reduced intravascular hemolysis due to exhaustive exercise in sedentary rats (32). We have now reported a decrease in oxidative stress and an alteration in the response of erythrocytes to exhaustive exercise in sedentary men who received antioxidant treatment for two months.

Increased plasma hemoglobin concentration and decreased haptoglobin levels, indicative of erythrocyte destruction, were detected in samples obtained from sedentary subjects 24 h after exhaustive exercise. Intravascular hemolysis was reported in several experiments as a consequence of exercise (32, 37, 42). The presence of intravascular hemolysis 24 hours after exercise suggests the maintenance of some destructive effects on erythrocytes. This might be based on increased osmotic fragility and reduced erythrocyte
deformability. We have previously observed a similar deterioration in erythrocytes after swimming or treadmill exercise protocols (32, 43). All observed results indicate that antioxidant vitamin treatment prevented the deleterious effects of exhaustive exercise on erythrocytes by decreasing exercise-induced oxidative stress.

Many studies have revealed that erythrocyte deformability is impaired early in the post-exercise period. Plasma volume alterations, increases in blood lactate level and alterations in cation concentrations of erythrocyte are major factors responsible for deteriorations of deformability after exercise (9). We found erythrocyte deformability to be impaired (i.e. higher SS_{1/2}) in both sedentary and trained groups 2 hours post exercise. This increase was significant before vitamin treatment in the sedentary group and after vitamin treatment in the trained group. In addition oxidative stress is also a factor that affects erythrocyte deformability during later periods after exercise in our study. Prevention of exercise-induced oxidative stress associated with decreased rates of erythrocyte destruction attained by antioxidant treatment, demonstrating the validity of this mechanism in sedentary men undergoing physical activity.

 Responses of Trained Subjects

Erythrocytes of trained subjects exhibited different responses to exhaustive cycling exercise compared to sedentary individuals before antioxidant treatment. Erythrocyte osmotic fragility and deformability values did not differ from basal 24 hours after the exercise session in the trained group. Similarly, intravascular hemolysis markers, plasma hemoglobin and haptoglobin concentrations, were not significantly changed after rigorous exercise. However, cycling exercise caused an increase in oxidative stress markers (TBARS and protein carbonyl content) before prior to antioxidant therapy. The presence of erythrocyte deterioration in sedentary subjects during post-exercise period, but not in trained subjects in spite of oxidative stress, indicates for a significant difference in erythrocyte properties between the two groups. As expected, the increase in TBARS and protein carbonyl content in trained subjects was also prevented by antioxidant treatment. However, antioxidant treatment did not alter the indices of erythrocyte mechanics and fragility.

Regular physical activity is known to enhance antioxidant enzymes’ activity primarily in striated muscle, heart and also in erythrocytes (19, 20, 26, 31). Only the CAT levels in our trained subjects were significantly higher than in sedentary subjects before the treatment period while the other enzymes measured did not exhibit significantly higher levels during both pre- and post treatment periods. Nevertheless, higher antioxidant enzyme levels could
not provide an explanation for different responses of erythrocytes to the exercise test as oxidative stress was apparent in both groups before antioxidant treatment. On the other hand, we did not examine low molecular weight biological compounds (such as glutathione, uric acid, bilirubin) that have antioxidant function (19), and may play a role in the observed discrepancies between the two groups. Erythrocytes from the trained group are more resistant to oxidative stress thus displaying an altered response.

The life expectancy of erythrocytes might also be another explanation for more resistant erythrocytes in our trained group. Trained people have a younger erythrocyte population than sedentary because regular physical activity shortens life span of erythrocytes (34, 37, 42). We performed density separation of erythrocytes as an approach to evaluate age distribution of red blood cells in our sedentary and trained groups. Elder erythrocytes become denser than younger cells and move to lower layers of density separation tubes. We determined that subjects in our trained group have significantly younger erythrocytes. By the reason that younger red blood cells are more resistant to oxidative stress (12), the response to exercise in trained individuals was different from that in sedentary group. In addition to their resistance to oxidative stress, younger erythrocytes have higher 2,3-diphosphoglycerate content and are more deformable, which may contribute to increased athletic performance (34). Therefore, oxidative stress occurring during exercise might be accepted as an adaptive mechanism, which supports the increased population of younger erythrocytes indirectly obtained by increased destruction of older erythrocytes.

In conclusion, exercise affects erythrocyte properties and leads to hemolysis by an oxidative mediated mechanism in sedentary, but not in exercise trained young men. Oxidative stress might be an important factor responsible for destruction of erythrocytes observed after acute, single bout rigorous training in sedentary subjects and/or at the beginning of training period.
